Abstract

We develop a novel filtering and estimation procedure for parametric option pricing models driven by general affine jump-diffusions. Our procedure is based on the comparison between an option-implied, model-free representation of the conditional log-characteristic function and the model-implied conditional log-characteristic function which is functionally affine in the model’s state vector. We formally derive a linear state space representation and establish the asymptotic properties of the corresponding measurement errors. The state space representation allows us to use suitably extended collapsed Kalman-type filtering techniques and brings important computational advantages. We analyze the finite-sample behavior of our procedure in Monte Carlo simulations. The applicability of our procedure is illustrated in two case studies that analyze S&P 500 option prices and the impact of exogenous state variables capturing Covid-19 reproduction and economic policy uncertainty.

1 Introduction

In this paper, we develop a new latent state filtering and parameter estimation procedure for option pricing models governed by general affine jump-diffusion processes. Our procedure leverages the linear relationship between the logarithm of an option-implied, model-free spanning formula for the conditional characteristic function and the state vector induced by the affine jump-diffusion model assumption. Linearity of the measurement and state updating equations of the resulting state space representation allows us to exploit Kalman-type filtering techniques. The proposed estimation procedure is theoretically justified and moreover fast and easy to implement, circumventing the typical computational burden when conducting inference on option pricing models.

Over the past decades, explosive growth in the trading of option contracts has attracted the attention of academics and practitioners to the development and estimation of increasingly sophisticated option pricing models. The building blocks of many continuous-time option pricing models are semimartingale stochastic processes that govern the dynamics of the underlying asset. These processes are often latent with stochastic diffusive volatility as the prototypical example, as in the classical Heston (1993) model. The literature also suggests the need to allow for a discontinuous jump component, both in the asset price dynamics and in its volatility process, potentially with a time-varying stochastic jump intensity.

An important econometric challenge lies in estimating the parameters of these continuous-time models and in filtering their unobserved and time-varying components, since option prices are highly nonlinear functions of the state vector. This stands in contrast to, for instance, term structure models, where bond yields can be represented as a linear function of the states, at least within the affine framework (see, e.g., Piazzesi 2010 for a review of the affine term structure literature). To obtain the option prices as a function of the state vector, one typically needs to apply either Fourier-based methods or simulation-based approaches. The price to pay in both cases is a substantial computational cost. This is one of the reasons why in much of the empirical research on option pricing, only a subset of the available option price data is used, such as at-the-money contracts or weekly (typically Wednesday) options data.

Exploiting the option-spanning formula of Carr and Madan (2001) for European-style payoff functions, we replicate the risk-neutral conditional characteristic function (CCF) of the underlying asset price at the expiration date in a completely model-independent way. In other words, we imply information about the CCF from the option prices without imposing any parametric assumptions on the underlying asset price dynamics. On the other hand, a large stream of literature is devoted to parametric option pricing models that often belong to the general affine jump-diffusion (AJD) family. The defining property of the AJD class is the exponential-affine joint CCF, which is available in semi-closed form. By comparing the two option pricing

1 A similar option-spanning approach for the CCF is used by Todorov (2019) to develop option-based non-parametric spot volatility estimates.
representations—model-free and model-implied—we can obtain a linear relation between the logarithm of the option-implied CCF and the model-dependent CCF within the affine framework.

When latent factors are present in the model specification, the linear relation enables us to exploit the rich literature on linear factor models. In particular, we extract the latent factors using suitably extended Kalman-type filtering techniques and estimate model parameters based on the associated quasi-maximum likelihood method. We provide a general state space representation for the AJD class of option pricing models. The resulting linear state space form allows us to leverage the Kalman filter to learn the unobserved intrinsic components of the model and estimate the model’s parameters using quasi-maximum likelihood. A similar approach is often used in the affine term structure literature, where the yields themselves are affine functions of the state vector (see, e.g., de Jong 2000, Driessen 2005, Duffee 1999). Besides the possibility to exploit Kalman-type filtering and estimation techniques, another advantage of our approach is that, once the model-free CCF has been obtained from the data, no further numerical option pricing methods, such as the FFT approach of Carr and Madan (1999) or simulation-based methods, are needed. Therefore, our method reduces computational costs considerably relative to many existing approaches in the option pricing literature. We note that whereas the parametric CCF is used to price options in Fourier-based methods, here we use the CCF to directly learn about the latent factors and model parameters.

We illustrate the developed estimation procedure in Monte Carlo simulations based on several AJD specifications. We consider both a one-factor AJD option pricing model, with latent stochastic volatility and jump intensities being affine functions of the stochastic volatility component, and a two-factor AJD model specification with an observable factor. We find good finite-sample performance in both cases.

Finally, we demonstrate our new filtering and estimation approach in an empirical application to S&P 500 index options. In particular, we filter and estimate the latent volatility from a stochastic volatility model with double-exponential jumps. We also investigate the impact of the Covid-19 propagation rate on the stock market within this model by embedding the reproduction number into the volatility and jump intensity dynamics. Our results show that while the reproduction numbers have a mild effect on total volatility, they contribute substantially to the likelihood of negative (but not positive) jumps. By contrast, when we consider an Economic Policy Uncertainty index as exogenous factor, the jump intensity process is not affected, but the exogenous factor contributes significantly to diffusive volatility.

Various estimation and filtering strategies for option pricing models have been developed in the literature. These include the (penalized) nonlinear least squares methods in, e.g., Bakshi, Cao, and Chen (1997), Broadie et al. (2007), Andersen, Fusari, and Todorov (2015); the efficient method of moments of Gallant and Tauchen (1996) as applied in Chernov and Ghysels (2000) and Andersen, Benzoni, and Lund (2002); the implied-state methods initiated by Pan (2002) and further analyzed by Santa-Clara and Yan (2010); the Markov Chain Monte Carlo method in Eraker (2004) and Eraker, Johannes, and Polson (2003); and the particle filtering method, see Johannes, Polson, and Stroud (2009) and Bardgett, Gourier, and Leippold (2019). Most of
these estimation methods use as inputs option prices or a monotonic transformation thereof, such as implied volatilities. By contrast, we propose an estimation procedure based on the prices of spanning option portfolios that contain all probabilistic information.

Estimation strategies based on the transform space of conditional characteristic functions are not new in the literature. For instance, Carrasco and Florens (2000) develop GMM estimation with a continuum of moment conditions based on the CCF; see also Singleton (2001). Carrasco, Chernov, Florens, and Ghysels (2007). In applications to option prices, Boswijk, Laeven, and Lalu (2015) and Boswijk, Laeven, Lalu, and Vladimirov (2021) propose to imply the latent state vector from a panel of options and then estimate the model via GMM with a continuum of moments. Bates (2006) develops maximum likelihood estimation with a filtration constructed using CCFs. In particular, he proposes a recursive likelihood evaluation by updating the CCF of a latent variable conditional upon observed data. However, unlike our approach, these methods suffer from a ‘curse of dimensionality’ since they require numerical integration over the dimension of the state vector.

Our work is also related to Feunou and Okou (2018), who exploit the linear relation between the four risk-neutral cumulants of the log-asset price and latent factors. They obtain these cumulants via a portfolio of options and employ the Kalman filter to estimate the latent factors. The main difference with our approach is that we use the CCF, instead of the first four moments. The CCF contains much richer information, leading to more efficient inference. Another difference is in dimension reduction: Feunou and Okou (2018) use a two-step PCA procedure to reduce the dimension of the risk-neutral cumulants observed at different maturities. Instead, we use a collapsed approach for the Kalman filter, originally developed by Jungbacker and Koopman (2015), which does not suffer from information losses relative to the full-dimensional setting.

The paper is organized as follows. Section 2 provides the theoretical framework for aligning the option-implied and model-implied CCFs of the underlying asset price. In Section 3, we develop the filtering approach and corresponding estimation procedure for the AJD option pricing models with latent state variables. Section 4 presents the Monte Carlo simulation results. We describe the data in Section 5 and demonstrate the empirical applications in Section 6. Conclusions are in Section 7. There are five appendices providing details on (i) the characteristic function replication, (ii) the measurement errors and the proof of Proposition 1, (iii) the computation of conditional moments, (iv) the extrapolation scheme for option prices, and (v) additional simulation and empirical results.

2 Theoretical Framework

In this section we provide the theoretical framework for our approach. We start with extracting information about the conditional characteristic function from options allowing for general underlying dynamics. Next, we consider the conditional characteristic function within the generalized AJD class, which is exponentially affine in the model’s state variables. Finally, we discuss how to align the two characteristic functions—option-implied model-free vs. AJD
model-implied—in order to make inferences about the parametric model fit and unobservable state variables.

2.1 Option-implied CCF

Throughout the paper, we fix a filtered probability space \((\Omega, \mathcal{F}, \{\mathcal{F}_t\}_{t \geq 0}, \mathbb{P})\). On this probability space, we consider the dynamics of an arbitrage-free financial market. The no-arbitrage assumption of the market guarantees the existence of the risk-neutral probability measure \(Q\), which is locally equivalent to \(\mathbb{P}\). Since we are interested in exploiting information from options, we formulate the model dynamics under \(Q\).

Let us denote by \(F_t\) the futures price at time \(t\) for a stock or an index futures contract with some fixed maturity. The absence of arbitrage implies that the futures price process is a semimartingale. In this subsection, we assume the following general dynamics for \(F_t\) under \(Q\):

\[
\frac{dF_t}{F_t} = v_t dW_t + \int x \tilde{\mu}(dt, dx),
\]

where \(v_t\) is an adapted, locally bounded, but otherwise unspecified stochastic volatility process; \(W_t\) is a standard Brownian motion, defined with respect to \(Q\); \(\mu\) is a counting random measure with compensator \(\nu_t(dx)dt\) such that \(\tilde{\mu}(dt, dx) := \mu(dt, dx) - \nu_t(dx)dt\) is the associated martingale measure and \(\int (x^2 \wedge 1) \nu_t(dx) < \infty\).

We further denote out-of-money (OTM) European-style option prices at time \(t\) with time-to-maturity \(\tau > 0\) and strike price \(K\) by

\[
O_t(\tau, K) = \begin{cases} 
E^Q[e^{-r\tau}(F_{t+\tau} - K)^+|\mathcal{F}_t], & \text{if } K > F_t \\
E^Q[e^{-r\tau}(K - F_{t+\tau})^+|\mathcal{F}_t], & \text{if } K \leq F_t.
\end{cases}
\]

The OTM price \(O_t(\tau, K)\) is a call option price if \(K > F_t\) and a put option price if \(K \leq F_t\). For simplicity we assume a constant interest rate \(r\).

Following Carr and Madan (2001), any twice continuously differentiable European-style payoff function \(g(F_{t+\tau})\) can be spanned via a position in risk-free bonds, futures (or stocks) and options with a continuum of strikes, as follows:

\[
g(F_{t+\tau}) = g(x) + g'(x)(F_{t+\tau} - x) + \int_0^x g''(K)(K - F_{t+\tau})^+dK + \int_x^\infty g''(K)(F_{t+\tau} - K)^+dK.
\]

Here, \(x \in \mathbb{R}^+\), the first and second terms on the right-hand side correspond to risk-free bonds and futures positions, and the third and fourth terms correspond to OTM options. Taking expectation under the risk-neutral measure for \(x = F_t\), we find that the price of a contingent claim with payoff function \(g(F_{t+\tau})\) discounted at time \(t\) can be expressed as a weighted portfolio of a risk-free bond and OTM options:

\[
E^Q[e^{-r\tau}g(F_{t+\tau})|\mathcal{F}_t] = e^{-r\tau}g(F_t) + \int_0^\infty g''(K)O_t(\tau, K)dK.
\]

This general spanning result lies behind the construction of one of most popular ‘fear’ indices—the VIX index, when \(g(F_{t+\tau}) = \log(F_{t+\tau}/F_t)\). Some other applications of the spanning
formula (2) include, for instance, the calculation of the option-implied skewness and kurtosis (Bakshi, Kapadia, & Madan, 2003) and the corridor implied volatility (Andersen & Bondarenko, 2007).

Applying this result to the complex-valued payoff function \( g(x) = e^{iu \log(x/F_t)} \) yields that the discounted conditional characteristic function (CCF) of log returns can be spanned as

\[
\phi_t(u, \tau) = e^{-r\tau}E_Q\left[ e^{iu \log(F_{t+\tau}/F_t)} \right] _{\mathcal{F}_t} = e^{-r\tau} - (u^2 + iu) \int_0^\infty \frac{1}{K^2} e^{iu \log(K - \log F_t)} \cdot O_t(\tau, K) dK
\]

\[
= e^{-r\tau} - (u^2 + iu) \frac{1}{F_t} \int_{\mathbb{R}} e^{(iu-1)m} \cdot O_t(\tau, m) dm,
\]

where \( m = \log \frac{K}{F_t} \) is the log-moneyness of an option with the strike price \( K \).

It is important to emphasize that the spanning of the CCF in equation (3) is exact and is completely model independent akin to the VIX. Therefore, the conditional characteristic function of log returns can be replicated in a model-free way given a single cross-sectional slice of liquid option prices with all strikes. A similar approach of CCF spanning is taken by Todorov (2019) to nonparametrically estimate spot volatilities from option prices.

The expression in (3) cannot be calculated analytically as we do not observe option prices for a continuum of strikes. Nevertheless, as we show in Appendix A, equation (3) is easy to approximate using a limited number of observable option prices (see equation (A.1) in Appendix A). In our empirical applications, we further employ an interpolation-extrapolation scheme to improve the reliability of the approximation and take into account the observation errors in option prices. Appendix A provides further details of this approximation. We denote by \( \hat{\phi}_t(u, \tau) \) the computationally feasible counterpart of the option-implied CCF.

### 2.2 Affine jump-diffusion CCF

The CCF of the log returns of the underlying asset is often considered under some parametric assumptions on the return dynamics. Hence, a model-implied CCF depends on the model parameters, that we generally do not know, and potentially on the dynamics of other latent processes, that affect the distribution of returns. Therefore, by aligning the model-free and parameter-dependent CCFs, we can learn model parameters and unobservable state dynamics.

We restrict our attention to a broad class of affine jump-diffusion (AJD) models defined in Duffie et al. (2000). The main attraction of the AJD class is that the Laplace transform has a semi-closed-form expression and is of the exponential-affine form. Suppose \( X_t \) is a Markov process representing a \( d_X \)-dimensional state vector in \( D \subset \mathbb{R}^{d_X} \) with the first component being the log price of an asset. We assume that under the physical and risk-neutral probability measures, the state vector \( X_t \) solves the following stochastic differential equation:

\[
dX_t = \mu(X_t; \theta) dt + \sigma(X_t; \theta) dW_t + \sum_{i=1}^{d_J} J_{i,t} dN_{i,t},
\]

where \( W_t \) is a standard Brownian motion in \( \mathbb{R}^{d_W} \); \( \mu: D \to \mathbb{R}^{d_X}, \sigma: D \to \mathbb{R}^{d_X \times d_W} \); \( J_{i,t} dN_{i,t} \) is a pure jump process with intensity \( \{\lambda^i(X_t; \theta); t \geq 0\} \) with \( \lambda^i: D \to \mathbb{R}^+ \) and jump size \( J_{i,t} \)
with conditional distribution $\nu^i$ on $\mathbb{R}^{d_X}$ for $i = \{1, \ldots, d_J\}$, and $\theta$ is the vector of unknown parameters that governs the model for $X_t$. The specification (4) can also be extended, for instance, to include infinite activity jumps and a time-dependent structure. See Duffie et al. (2000) and Duffie, Filipović, and Schachermayer (2003) for more details on the AJD class formulation.

Following Duffie et al. (2000), the drift $\mu(x)$, diffusive variance $\sigma(x)\sigma(x)^T$ and jump intensities $\lambda^i(x)$ are assumed to be affine on $D$:

$$
\begin{align*}
\mu(x) &= K_0 + K_1 x, & K_0 \in \mathbb{R}^{d_X}, K_1 \in \mathbb{R}^{d_X \times d_X}, \\
\sigma(x)\sigma(x)^T &= H_0 + \sum_{j=1}^{d_X} x_j H_1^{(j)}, & H_0 \in \mathbb{R}^{d_X \times d_X}, H_1^{(j)} \in \mathbb{R}^{d_X \times d_X}, j = \{1, \ldots, d_X\}, \\
\lambda^i(x) &= l_{i,0} + l_{i,1} \cdot x, & l_{i,0} \in \mathbb{R}, l_{i,1} \in \mathbb{R}^{d_X}, i = \{1, \ldots, d_J\},
\end{align*}
$$

where $x_j$ is the $j$-th element of a vector $x$ and $H_1^{(j)}$ for $j=1, \ldots, d_X$ form a $d_X \times d_X \times d_X$ tensor $H_1$ by stacking matrices along a new dimension. The joint regularity conditions on $(D, \mu, \sigma, \lambda, \nu)$, that guarantee a unique solution to the SDE (4), are discussed in Duffie and Kan (1996) and Dai and Singleton (2000). These joint conditions put constraints on the parameter vector $\theta$. Therefore, we consider a model from the AJD class indexed by $\theta$ in a parameter space $\Theta$ containing such admissible parameter values, on which there is a unique solution to (4) that remains in $D$. For instance, in the case of the stochastic volatility component, the admissible parameter values in $\Theta$ ensure that the volatility process remains nonnegative, by satisfying the Feller condition. See also the discussion of the admissibility problem in Singleton (2006, Chapter 5).

Duffie et al. (2000) show that the affine dependence of the functions $\mu(x)$, $\sigma(x)\sigma(x)^T$ and $\lambda(x)$ implies an exponential-affine form of the CCF of the state vector $X_t$. Specifically, the discounted joint CCF of $X_{t+\tau}$ conditional on $\mathcal{F}_t$ with $\tau > 0$ is given by

$$
\phi(u, X_t) = e^{-\tau T} \mathbb{E}^\mathbb{Q}[e^{iu \cdot X_{t+\tau}} | \mathcal{F}_t] = e^{\alpha(u, \tau; \theta) + \beta(u, \tau; \theta) \cdot X_t},
$$

(5)

where $u \in \mathbb{R}^{d_X}$ is an argument vector and $\alpha(u, \tau; \theta)$ and $\beta(u, \tau; \theta)$ are solutions to the following complex-valued ODE system in time:

$$
\begin{align*}
\dot{\beta}(s) &= K_0^T \beta(s) + \frac{1}{2} \beta(s)^T H_1 \beta(s) + \sum_{i=1}^{d_J} l_1^i (\chi^i(\beta(s)) - 1), \\
\dot{\alpha}(s) &= K_0^T \beta(s) + \frac{1}{2} \beta(s)^T H_0 \beta(s) + \sum_{i=1}^{d_J} l_0^i (\chi^i(\beta(s)) - 1) - r,
\end{align*}
$$

(6)

with initial conditions $\beta(0) = iu$ and $\alpha(0) = 0$. Here, $\chi^i(c) = \int_{\mathbb{R}^n} \exp(c \cdot z) d\nu^i(z)$, $c \in \mathbb{C}^{d_X}$ are jump transforms, that determine the conditional jump-size distributions. The ODE for $\beta$ is known as the generalized Riccati equation, while the solution for the second ODE can be obtained by simply integrating the right-hand side expression over time.

The affine dependence of the characteristic exponent $\alpha(u, \tau; \theta) + \beta(u, \tau; \theta) \cdot X_t$ on the current state $X_t$ is the defining property of the AJD class under some regularity conditions (see Duffie et al. 2003). In other words, the AJD can be defined as a class in which characteristic exponents of $X_{t+\tau}$ given $X_t$ are affine functions with respect to $X_t$. In fact, this is a key property in our
Unlike the option-implied CCF (3), the CCF in (5) is fully parametric, that is, it requires a parametric AJD model dynamics of the state vector \( X_t \). Although the AJD class is more restrictive than the general dynamics of \( F_t \) in (1), it includes a myriad of popular option-pricing models such as in Heston (1993), Duffie et al. (2000), Pan (2002), Bates (2006), Broadie et al. (2007), (Boswijk et al., 2015), and Andersen et al. (2017) among many others.

The state process \( X_t \) might include both observed and unobserved state variables that affect the dynamics of the log futures returns \( \log F_t \). In our empirical application, we consider the presence of both. Therefore, it is convenient to partition the state vector as \( X'_t = (w'_t, x'_t) \), where \( w_t \) represents the observable component and \( x_t \) includes \( d < d_X \) latent state variables. Then, the dynamics \( X_t \), given by equation (4) can be rewritten as

\[
dw_t = \mu^w(w_t, x_t)dt + \sigma^w(w_t, x_t)dW_t + \sum_{i=1}^{d_J} J^w_{i,t}dN_{i,t},
\]

\[
dx_t = \mu^x(w_t, x_t)dt + \sigma^x(w_t, x_t)dW_t + \sum_{i=1}^{d_J} J^x_{i,t}dN_{i,t},
\]

where \( \mu^w: D \to \mathbb{R}^{dX-d} \), \( \mu^x: D \to \mathbb{R}^d \), \( \sigma^w: D \to \mathbb{R}^{(dX-d) \times dJ} \), \( \sigma^x: D \to \mathbb{R}^{d \times dJ} \) and \( J^w_{i,t} \) and \( J^x_{i,t} \) are marginal jump sizes of \( J_{i,t} \) associated with \( w_t \) and \( x_t \), respectively. In the simplest case, the observable component includes only the log futures prices, that is, \( w_t = \log F_t \). In more general settings, the stochastic volatility is often the main latent driver of the log returns dynamics, as e.g., in Heston (1993).

### 2.3 Marrying the two CCFs

Given the two CCFs (3) and (5), we can now align them to conduct inferences about the parametric model fit and unobservable state variables. For that purpose, first note that the CCF in (5) is joint for the state vector \( X_t \). Recall that we assume, without loss of generality, that the first component of the state vector \( X_t \) is the log futures price. Therefore, we can easily obtain its marginal CCF by plugging in an argument vector of the form \( u_1 := (u, 0, \ldots, 0)' \in \mathbb{R}^{dX} \) with \( u \in \mathbb{R} \). To obtain the marginal CCF for the log returns, we further subtract the term \( iu \log F_t \) in the exponent. That is, the marginal CCF of log returns under the AJD specification is as follows:

\[
\phi_t^{AJD}(u, \tau) = e^{-\tau r} \mathbb{E}^Q \left[ e^{iu_1 X_{t+\tau} - iu \log F_t} \big| F_t \right] = e^{\alpha(u_1, \tau; \theta) + \tilde{\beta}(u_1, \tau; \theta) \cdot X_t},
\]

where \( \tilde{\beta}(u_1, \tau; \theta) := \beta(u_1, \tau; \theta) - iu_1 \); that is, \( \tilde{\beta}(u_1, \tau; \theta) \) has only the first component different from \( \beta(u_1, \tau; \theta) \) since we are interested in the CCF of log returns rather than log prices.

Note that the log of the (joint) CCF (also known as cumulant-generating function) is linear in the state vector \( X_t \). Therefore, under the correctly specified AJD model we obtain a simple
linear relation between the log of the option-spanned CCF\(^4\) of log returns and the model’s state vector:

\[
\log \phi_t(u, \tau) = \alpha(u_1, \tau; \theta) + \tilde{\beta}(u_1, \tau; \theta) \cdot X_t. \tag{10}
\]

Replacing the cumulant generating function on the left-hand side with its computationally feasible counterpart \(\hat{\phi}_t(u, \tau)\) (see the discussion in Appendix A), we obtain the following equation, which will play a central role in our estimation procedure:

\[
\log \hat{\phi}_t(u, \tau) = \alpha(u_1, \tau; \theta) + \tilde{\beta}(u_1, \tau; \theta) \cdot X_t + \xi_t(u, \tau), \quad u \in \mathbb{R}, \tag{11}
\]

where \(\xi_t(u, \tau)\) is the measurement error, which is related to the observation, discretization and truncation errors in the option-spanning CCF calculations. We elaborate on the relation between the computable counterpart of the CCF and the source of the measurement errors in the next section.

Equation (11) is the key relation in our analysis and a few remarks shall be made here regarding it. First of all, equation (11) is essentially a functional linear model since this equation holds for any argument variable of the CCF, \(u \in \mathbb{R}\). Furthermore, the functions \(\alpha(u_1, \tau; \theta)\) and \(\tilde{\beta}(u_1, \tau; \theta)\) are parameter-dependent and solutions to the system of Riccati ODEs (6). Therefore, if the state vector \(X_t\) is observable, then the model parameters can be obtained by solving a continuum version of a non-linear least-squares problem.

In the case when the state vector is latent, equation (11) represents a linear factor model with a continuum number of linear relations. The factors are the state components of the AJD model. Therefore, we could apply, for instance, a (functional) principal component analysis to learn the unobserved factors. In this paper, we utilize the classical Kalman filtering technique to estimate both model parameters and latent factors.

In other words, equation (11) reveals that AJD models, often formulated in continuous time, may be estimated using well-studied approaches from the rich literature on linear factor and state space models. Also, in a similar way, bond yields are linear functions of the state vector in affine term structure models (see Piazzesi (2010) for a review of this class of models). For instance, Duffee (1999), de Jong (2000), Driessen (2005) use the Kalman filter in their estimation of affine term structure models.

Furthermore, another advantage of this approach is that it does not require to price options given a certain parametric model. This estimation approach is more computationally appealing compared to many other alternative approaches, that often involve the Carr-Madan FFT pricer (Carr & Madan 1999) or the COS method (Fang & Oosterlee, 2008) to price options. This also implies that the usage of the characteristic function is different: with the FFT or COS method one needs a model-dependent CCF only to price options, while here we use the CCF to directly learn the latent factors and model parameters.

\(^4\)Although the logarithm of a complex number is a multivalued function, here, the ambiguity is resolved given the fact that \(\phi(0) = 1\) and the CCF is a continuous function. In fact, in practice we ensure that the logarithm of the CCF does not have ‘jumps’ by taking the logarithm sequentially with respect to \(u\), starting from the origin.
Finally, given the partition of the state vector into observable and unobservable components, the linear relation between the option-implied and model-implied CCFs can be rewritten as
\[
\log \hat{\phi}(u, \tau) = \alpha(u_1, \tau; \theta) + \beta^w(u_1, \tau; \theta) \cdot w_t + \beta^x(u_1, \tau; \theta) \cdot x_t + \xi_t(u, \tau), \quad u \in \mathbb{R},
\]
where \(\beta^w(u_1, \tau; \theta) \in \mathbb{C}^{d \times d}\) and \(\beta^x(u_1, \tau; \theta) \in \mathbb{C}^d\) are such that \(\tilde{\beta}^T = (\beta^w^T, \beta^x^T)\) is the solution to the ODE system \([6]\). Representation \((12)\) serves as a basis for an observation (or measurement) equation in our estimation procedure.

### 3 Estimation Procedure

In this section, we develop our filtering approach and corresponding estimation procedure for the general class of AJD models under consideration. First, we provide the state space representation for the defined class of models. Then, we detail our estimation strategy using the collapsed Kalman filter.

#### 3.1 State space representation

As discussed in the previous section, we restrict our attention to the parametric models of the AJD class due to their exponential-affine form of the characteristic function. This form will allow us to exploit the linearized Kalman filter in the estimation procedure. In the following, we summarize the assumptions we impose on the parametric model:

**Assumption 1** (i) The stochastic process \(X_t\) is Markov and affine process with finite second moments under both the physical and risk-neutral probability measures \(P\) and \(Q\). In particular, \(X_t\) is the unique solution to the SDE \([4]\) and its characteristic function is of the exponential-affine form \([5]\);

(ii) The true parameter vector \(\theta_0\) lies in the interior of a compact parameter space \(\Theta\) containing admissible parameter values.

Assumption 1 jointly guarantees the existence of a unique solution to the SDE \([4]\) within the AJD class. As discussed in Section 2.2, admissible values \(\theta \in \Theta\) reflect the regularity conditions imposed on the elements of the AJD representation such that there is a unique solution to \([4]\). For instance, it imposes the Feller condition for the stochastic volatility and non-negative jump sizes for volatility jumps. In general, the admissibility conditions will need to be checked in a case-by-case model analysis. Assumption 1(i) also presumes the technical conditions required to represent the AJD process, defined via the affine dependence of its drift, diffusive variance and jump intensities on the state vector, via the exponential-affine characteristic function. For a detailed analysis of the AJD theory we refer to Duffie et al. (2000) and Duffie et al. (2003).

In our estimation procedure we discretize the continuous-time model along two dimensions: with respect to time and with respect to the arguments of the CCF. The former naturally follows from the discrete observations of financial data, which we denote by the integer indices \(t = 1, \ldots, T\). The latter allows us to rely on the existing literature about filtering techniques.
For that, let us denote the collection of the discretely sampled arguments as a set $U \subseteq \mathbb{R}$ with cardinality $q \in \mathbb{N}$. We further consider options with $k \in \mathbb{N}$ different time-to-maturities $\tau$ and $n \in \mathbb{N}$ different log-moneyness values $m$ on each day.

Since the inputs of our estimation procedure are the portfolio of options, we need to take into account the errors of these options portfolios. For that purpose, we assume the observation error scheme on the option prices that constitute the portfolios. The measurement errors will be defined on the common probability space $(\Omega, \mathcal{F}, \mathbb{P})$, but in what follows, the filtration $\{\mathcal{F}_t\}_{t \geq 0}$ is generated by the state process $\{X_t\}_{t \geq 0}$ only. Note that the theoretical option prices $O_t(\tau, m)$ are $\mathcal{F}_t$-measurable, and hence also functionals of the option prices such as the (theoretical) Black-Scholes implied volatility and vega.

**Assumption 2** Option prices are observed with an additive error term:

$$\hat{O}_t(\tau_i, m_j) = O_t(\tau_i, m_j) + \zeta_t(\tau, m), \quad t = 1, \ldots, T, \quad i = 1, \ldots, k, \quad j = 1, \ldots, n,$$

where the observation errors $\zeta_t(\tau, m)$ are such that:

(i) $\zeta_t(\tau, m)$ are $\mathcal{F}_t$-conditionally independent along tenors $\tau$, moneyness $m$ and time $t$;

(ii) $\mathbb{E}[\zeta_t(\tau, m)|\mathcal{F}_t] = 0$;

(iii) $\mathbb{E}[\zeta_t^2(\tau, m)|\mathcal{F}_t] = \sigma_t^2(\tau, m) < \infty$ with $\sigma_t(\tau, m) := \sigma_\kappa(\tau, m)\nu_t(\tau, m)$, where $\sigma_\kappa \in \mathbb{R}^+$, $\kappa_t(\tau, m)$ is the Black-Scholes implied volatility, and $\nu_t(\tau, m)$ is the Black-Scholes vega.

The additive error assumption is commonly imposed in the option pricing literature. For instance, Andersen et al. (2015) and Todorov (2019) use additive error assumptions for option prices quoted in terms of BSIV and dollar amount, respectively. Additive observation errors are also often implicitly assumed when calibrating an option pricing model to market-observed prices, since the calibration is often performed using non-linear least squares as in, e.g., Broadie et al. (2007).

Assumption 2(i) excludes dependence of the observation errors across strikes and is also often imposed in the literature (see, for instance, Christoffersen, Jacobs, & Mimouni, 2010, Andersen et al., 2015 and Todorov, 2019). This assumption can be relaxed by introducing a spatial dependence as in Andersen, Fusari, Todorov, and Varneskov (2021). This would, however, result in more complex expressions for the covariance terms in the measurement errors, that we derive below. Furthermore, Andersen et al. (2021) find evidence of limited dependence in the observation errors for S&P 500 index options. They also show that this dependence declined sharply for short-dated options in recent years due to improved liquidity. Since in our empirical application we consider S&P 500 index options with short tenors focusing on the last three years, the independence assumption will play a secondary role for the estimation procedure.

The conditional mean zero Assumption 2(ii) is crucial for our main result. Assumption 2(iii) asserts the standard deviation of the observation errors to be proportional to the product of the option’s BSIV and vega. The motivation for this structure is as follows. Let $\tilde{\kappa}(m_j)$ and $\kappa(m_j)$ denote the error-distorted and true BSIV of an option, and assume that the relative volatility errors $\kappa = (\tilde{\kappa}(m_j) - \kappa(m_j)) / \kappa(m_j)$ are homoskedastic across the strikes, such that $\mathbb{E}[\kappa^2_t|\mathcal{F}_t] = \sigma_\kappa^2$. 

11
A Taylor-series expansion of the BS pricing function $O^{BS}(\tilde{\kappa}(m_j), m_j)$ around $\kappa(m_j)$ then gives
\[
\tilde{O}(m_j) = O^{BS}(\tilde{\kappa}(m_j), m_j) \approx O(m_j) + \nu(m_j) \kappa(m_j) x_j,
\]
with $\nu(m_j) = \partial O^{BS}(\kappa(m_j), m_j)/\partial \kappa(m_j)$, the theoretical BS vega. Homoskedastic errors in relative implied volatilities are also assumed by Christoffersen, Jacobs, and Ornthanalai (2012) and Du and Luo (2019) in their MLE based on the particle filter and UKF, respectively.

Finally, to assess the CCF approximation error sizes, we impose the following assumption on the existence of moments for the underlying asset and on log-moneyness grid that allows nonequidistant sampling:

**Assumption 3**
(i) The underlying process and its reciprocal process have finite second moments under the risk-neutral measure: $\mathbb{E}^Q[\tau^{2}\mid \mathcal{F}_t] < \infty$ and $\mathbb{E}^Q[\tau^{-2}\mid \mathcal{F}_t] < \infty$ with $\tau > 0$;

(ii) For the log-moneyness grid $\{m_j\}_{j=1}^n$, there exists a deterministic sequence $\Delta m$ such that $\Delta m \rightarrow 0$ as $n \rightarrow \infty$ and
\[
\eta \Delta m \leq \inf_{j=2, \ldots, n} \Delta m_j \leq \sup_{j=2, \ldots, n} \Delta m_j \leq \Delta m,
\]
where $\Delta m_j := m_j - m_{j-1}$ and $\eta \in (0, 1]$ is some constant.

Given $n > 1$ observable option prices with time-to-maturity $\tau > 0$ and log-moneyness values $m_1 < \ldots < m_n$, we may approximate the CCF $\phi_t(u, \tau)$ given in (3) by replacing the theoretical option prices by their observed versions, and the integral by a Riemann sum:
\[
\hat{\phi}_t(u, \tau) = e^{-r \tau} - u_t \sum_{j=2}^n e^{(iu-1)m_j} \cdot \hat{O}_t(\tau, m_j) \Delta m_j,
\]
where we use the notation $u_t := (u^2 + iu) \frac{1}{\mathcal{F}_t}$ and $\hat{O}_t(\tau, m_j)$ satisfies Assumption 2.

The deviation of the option-spanned CCF from its theoretical counterpart, $\zeta_t^{(u, \tau)} := \hat{\phi}_t(u, \tau) - \phi_t(u, \tau)$ stems from observation, truncation and discretization errors (where truncation refers to the fact that the integration interval $[m_1, m_n]$ does not cover the entire real line). The discretization and truncation errors depend on the availability of option prices, but they can be efficiently reduced by using an interpolation-extrapolation scheme (see, e.g., Jiang & Tian 2005, Jiang & Tian 2007 and Chang, Christoffersen, Jacobs, & Vainberg 2012), and taking the limit as $n \rightarrow \infty$. A further analysis of this approximation is provided in Appendix A. As we show in Appendix B, the observation errors will dominate the discretization and truncation errors and we will be taking them into account in the estimation procedure.

From the preceding analysis, the functional measurement equation (12) is obtained from the following log-linearization:
\[
\xi_t(u, \tau) := \log \hat{\phi}_t(u, \tau) - \log \phi_t(u, \tau) = \log \left(1 + \frac{\zeta_t(u, \tau)}{\phi_t(u, \tau)}\right) = \xi_t^{(1)}(u, \tau) + r_t(u, \tau),
\]
where $r_t(u, \tau)$ is the remainder term after the observation errors $\xi_t^{(1)}(u, \tau) := \frac{\zeta_t^{(1)}(u, \tau)}{\phi_t(u, \tau)}$ with
\[
\zeta_t^{(1)}(u, \tau) = -u_t \sum_{j=2}^n e^{(iu-1)m_j} \cdot \xi_t(\tau, m_j) \Delta m_j.
\]
We note that the remainder term collects the log-linearization of the truncation and discretization errors and higher-order terms from a Taylor-series expansion.

To formulate the main result, we turn the functional measurement equation (12) into a vector measurement equation, as usual in state space model formulations. First, we stack the log CCF and the corresponding measurement errors along $q$ values $u_1, \ldots, u_q$ for the CCF argument $u \in \mathcal{U}$, for a fixed expiration period $\tau_i$:

$$
\log \hat{\phi}_{t,i} := \begin{pmatrix}
\log \hat{\phi}_t(u_1, \tau_i) \\
\log \hat{\phi}_t(u_2, \tau_i) \\
\vdots \\
\log \hat{\phi}_t(u_q, \tau_i)
\end{pmatrix}, \quad \xi_{t,i} := \begin{pmatrix}
\xi_t(u_1, \tau_i) \\
\xi_t(u_2, \tau_i) \\
\vdots \\
\xi_t(u_q, \tau_i)
\end{pmatrix}.
$$

Next, to tackle the complex-valued observation equation (12) with a real-valued state vector, we stack the real and imaginary parts without losing information. For that, we denote by $a_{t,i}, b_{t,i}^w$ and $b_{t,i}^r$, the stacked outputs of the functions $\alpha_t(u, \tau_i), \beta_t^w(u, \tau_i)$ and $\beta_t^r(u, \tau_i)$, respectively. Then, we obtain the measurement equation by stacking its real and imaginary parts as well as $k$ time-to-maturities:

$$
\begin{pmatrix}
\Re(\log \hat{\phi}_{t,1}) \\
\Im(\log \hat{\phi}_{t,1}) \\
\vdots \\
\Re(\log \hat{\phi}_{t,k}) \\
\Im(\log \hat{\phi}_{t,k})
\end{pmatrix} = \begin{pmatrix}
\Re(a_{t,1}) \\
\Im(a_{t,1}) \\
\vdots \\
\Re(a_{t,k}) \\
\Im(a_{t,k})
\end{pmatrix} + \begin{pmatrix}
\Re(b_{t,1}^w) \\
\Im(b_{t,1}^w) \\
\vdots \\
\Re(b_{t,k}^w) \\
\Im(b_{t,k}^w)
\end{pmatrix} w_t + \begin{pmatrix}
\Re(b_{t,1}^r) \\
\Im(b_{t,1}^r) \\
\vdots \\
\Re(b_{t,k}^r) \\
\Im(b_{t,k}^r)
\end{pmatrix} x_t + \begin{pmatrix}
\Re(\xi_{t,1}) \\
\Im(\xi_{t,1}) \\
\vdots \\
\Re(\xi_{t,k}) \\
\Im(\xi_{t,k})
\end{pmatrix}, \quad (16)
$$

where $p = 2qk$. The stacked observation equation (16) links all available information from option prices with several tenors at time $t$ to the state vectors $w_t$ and $x_t$ in a linear way.

To complete the state space model we need to augment the measurement equation (16) by a transition equation for the unobservable state vector $x_t$. This is a linear, discrete-time dynamic system, to be derived from the continuous-time stochastic differential equation. An Euler discretization of the state process (8) would converge to the true transition dynamics as the discretization step $\Delta t \to 0$. However, the maximum likelihood (ML) estimator based on the Euler discretization is, in general, inconsistent for fixed non-zero $\Delta t$ (Lo, 1988), because the discretization has conditional moments different from those of the true process (Piazzesi, 2010). Fortunately, the AJD assumption implies that the first and second conditional moments of $x_{t+1}$ given $\mathcal{F}_t$ are linear and available in semi-closed form (possibly requiring the solution of a system of ODEs):

$$
\mathbb{E}[x_{t+1}|\mathcal{F}_t] = c_t + T_t x_t, \quad (17)
$$

$$
\text{Var}(x_{t+1}|\mathcal{F}_t) = Q_t(x_t), \quad (18)
$$

A complex-valued state vector would have required to consider a complex Kalman filter based on the so-called widely linear complex estimator as in Dini and Mandic (2012).

See Singleton (2001) and Chacko and Viceira (2003), who use this approach in a GMM estimation setting based on the empirical characteristic function.
where $Q_t: \mathbb{R}^d \to \mathbb{R}^{d \times d}$ is an affine function in $x_t$. The finiteness of the conditional moments is ensured by Assumption 1(ii). Both conditional moments will in general be linear in both the observed state $w_t$ and the latent state $x_t$; but because the former does not need filtering, we absorb its effect in the time-varying intercept $c_t$, and similarly in the intercept of the affine function $Q_t$. In Appendix C, we show how these transition coefficients can be computed for the AJD model. Using this approach, which will be model-dependent and hence has to be applied case by case, we obtain a discrete-time transition equation with the same conditional mean and variance as the true continuous-time process (but possible different higher moments). Quasi-maximum likelihood (QML) estimation based on conditionally normally distributed measurement and transition errors in the state space representation yields consistent estimation results (Fisher & Gilles 1996). A similar approach has been adopted in the term structure literature (see, e.g., de Jong 2000, Duffee 2002).

We summarize the development of the state space representation, and analyze properties of the errors, in the following proposition. The main result contains a remainder term in the measurement equation that collects the truncation and discretization errors in the construction of $\log \hat{\phi}(u, \tau)$ and higher-order terms in the log-linearization. This term vanishes under an asymptotic scheme, where $m := \max_{1 \leq j \leq n} m_j \to \infty$, $m := \min_{1 \leq j \leq n} m_j \to -\infty$ and $\Delta m \to 0$. We also denote the corresponding smallest and largest strike prices as $K$ and $\bar{K}$, and express the asymptotic orders with respect to the number of option prices $n$ with fixed maturity.

**Proposition 1** Suppose Assumptions 1, 2 and 3 hold, and in addition $K \asymp n^{-\alpha}$ and $\bar{K} \asymp n^\alpha$ with $\alpha > 0$ and $\bar{\alpha} > 0$. Then $\{y_t, x_t, t = 1, \ldots, T\}$ satisfy the linear state space representation

\[
\begin{align*}
y_t &= d_t + Z_t x_t + r_{t,n} + \varepsilon_t, \quad \mathbb{E}[\varepsilon_t | F_t] = 0, \quad \mathbb{E}[\varepsilon_t \varepsilon_t' | F_t] = H_t, \\
x_{t+1} &= c_t + T_t x_t + \eta_{t+1}, \quad \mathbb{E}[\eta_{t+1} | F_t] = 0, \quad \mathbb{E}[\eta_{t+1} \eta_{t+1}' | F_t] = Q_t(x_t),
\end{align*}
\]

where $r_{t,n} = \mathcal{O}_p \left( n^{-2(\alpha/\bar{\alpha})} \sqrt{\log n} \right)$ and $\varepsilon_t = \mathcal{O}_p \left( \sqrt{\log n} \right)$; $d_t = \tilde{d}_t + W_t w_t$ and $Z_t$ are defined in (16) and $c_t$, $T_t$ and $Q_t$ are as given in (17)-(18); and $H_t = \text{blkdiag}(H_{t,1}, \ldots, H_{t,k})$, with

\[
H_{t,i} = \sigma_\varepsilon^2 \left( \frac{1}{2} \Re (\tilde{\Gamma}_{t,i} - \tilde{C}_{t,i}) + \frac{1}{2} \Im (\tilde{\Gamma}_{t,i} + \tilde{C}_{t,i}) \right), \quad i = 1, \ldots, k,
\]

where $\tilde{\Gamma}_{t,i}$ and $\tilde{C}_{t,i}$ are covariance and pseudo-covariance matrices of $\xi_{i,t}/\sigma_\varepsilon$, with elements

\[
(\tilde{\Gamma}_{t,i})_{kl} = \frac{u_{k,t} u_{l,t} \sum_{j=2}^{n} e^{\frac{(i(u_k - u_l)^{-2}) m_j}{2}} \bar{\nu}_l^2(\tau_i, m_j)(\Delta m_j)^2}{\phi_t(u_k, \tau_i) \phi_t(u_l, \tau_i)}, \quad k, l = 1, \ldots, q,
\]

and

\[
(\tilde{C}_{t,i})_{kl} = \frac{u_{k,t} u_{l,t} \sum_{j=2}^{n} e^{\frac{(i(u_k + u_l)^{-2}) m_j}{2}} \bar{\nu}_l^2(\tau_i, m_j)(\Delta m_j)^2}{\phi_t(u_k, \tau_i) \phi_t(u_l, \tau_i)}, \quad k, l = 1, \ldots, q.
\]

Furthermore,

(i) $\mathbb{E}[\varepsilon_t \varepsilon_t'] = 0$ and $\mathbb{E}[\eta_t \eta_t'] = 0$ for $s \neq t = 1, \ldots, T$.

---

7 The transition matrix $T_t$ will not be time-varying in stationary AJD process with equidistant observations, but we do not impose this time-constancy in the notation, also to avoid confusion with the sample size $T$. 

---

14
\((ii)\) \(E[\varepsilon_t\eta_t'] = 0\) for all \(s, t = 1, \ldots, T;\)

\((iii)\) \(E[\varepsilon_t x_t^2] = 0\) and \(E[\eta_{t+1} x_t^2] = 0\) for \(t = 1, \ldots, T.\)

The proof is given in Appendix [B]. The orders suggest that the remainder term goes to zero faster than the observation term, we need minimum non-zero requirements for \(\alpha\) and \(\bar{\alpha}\). In what follows, we assume that \((\alpha \lor \bar{\alpha}) > \frac{1}{4}\) and neglect the remainder term in the estimation and filtering procedures. Note that the system matrices \(Z_t, T_t, Q_t(x_t)\) and system vectors \(d_t\) and \(c_t\) are known up to a parameter vector \(\theta\), assumed to lie in the interior of a compact parameter space \(\Theta\) by Assumption [I](iii). Similarly, the system matrix \(H_t\) depends on the data and \(\theta\) (via \(u_t, \phi_t, \kappa_t\) and \(\nu_t\)), and an additional unknown parameter \(\sigma^2_{\kappa_t}\). Estimation of \(\theta\) and filtering of the latent state vector via (versions of) the Kalman filter is considered in the next sub-section.

### 3.2 Modified and Collapsed Kalman filter

Consider the state space representation (19)–(20), where from now on we will ignore the remainder term \(r_{t,n}\), and hence assume that the set of strike prices \(\{m_j\}_{j=1}^n\) on each day is rich enough to make this term negligible. Define \(Y_t = \{y_1, \ldots, y_t\}\), and linear projections (denoted \(\hat{E}\)) of the state vector conditional on the data: \(\hat{x}_{t|t} = \hat{E}[x_t|Y_t]\) and \(\hat{x}_{t|t-1} = \hat{E}[x_t|Y_{t-1}]\), with corresponding mean square error matrices \(P_{t|t} = \hat{E}[(x_t-x_{t|t})(x_t-x_{t|t})']\) and \(P_{t|t-1} = \hat{E}[(x_t-x_{t|t-1})(x_t-x_{t|t-1})']\). Then a modified version of the Kalman filter reads as follows:

\[
\begin{align*}
v_t &= y_t - (d_t + Z_t\hat{x}_{t|t-1}), \\
\hat{x}_{t|t} &= \hat{x}_{t|t-1} + P_{t|t-1}Z_t'F_t^{-1}v_t, \\
\hat{x}_{t+1|t} &= c_t + T_t\hat{x}_{t|t},
\end{align*}
\]

\[
\begin{align*}
F_t &= Z_tP_{t|t-1}Z_t' + H_t, \\
P_{t|t} &= P_{t|t-1} - P_{t|t-1}Z_t'F_t^{-1}Z_tP_{t|t-1}, \\
P_{t+1|t} &= T_tP_{t|t}T_t' + Q_t(\hat{x}_{t|t}),
\end{align*}
\]

for \(t = 1, \ldots, T.\) Given the stationarity of the process, the initial conditions \(x_{1|0}\) and \(P_{1|0}\) for the filter can be set to the unconditional mean and variance, respectively.

Because the error terms in the measurement and transition equations are not assumed to be Gaussian, the filtered state \(\hat{x}_{t|t}\) in conventional linear homoskedastic state space models is the linear projection (or minimum mean square error linear predictor) of the true process \(x_t\), rather than its conditional expectation. This can be used to prove that quasi-maximum likelihood (QML) estimation based on the Gaussian likelihood yields consistent and asymptotically normal parameter estimates [Hamilton 1994, Chapter 13]. However, in general AJD models, the conditional variance \(Q_t(x_t)\) is an affine function of the true latent state vector \(x_t\). Therefore, the Kalman filter recursions have been modified by using \(Q_t(\hat{x}_{t|t})\) instead of the unobserved \(Q_t(x_t)\). A similar modification is used in, e.g., de Jong [2000], Monfort, Pegoraro, Renne, and Roussellet [2017] and Fournou and Okou [2018]. Although consistency of QML based on this modification has not been proved, Monte Carlo simulation results in these articles suggest that the method works well in practice.

Given the large dimension of the observation vector \(p = 2qk\), the Kalman filter and its QML estimation will be computationally challenging if not infeasible. In fact, an important caveat with this approach is that one needs a non-singular innovation variance matrix \(F_t\). Since our
CCF approximation is based on common option price data for \( q \) different arguments \( u \) and fixed
time-to-maturity \( \tau \), this matrix is likely to be (near-)singular for large \( q \). Furthermore, with
large cross-sectional dimension, the computation of the inverse matrix for each time \( t \) adds a
significant computational burden to the estimation procedure. To overcome these issues we
consider the collapsed Kalman filter, originally developed by Jungbacker and Koopman (2015),
which we describe below. We extend their method to allow for a (near-)singular variance matrix
\( H_t \), using generalized inverses.

The idea of the collapsed Kalman filter is to transform the observation vector \( y_t \) into an
uncorrelated pair of vectors \( y^*_t \) and \( y^+_t \) such that the first vector \( y^*_t \) depends on the state vector
\( x_t \) and has dimension \( d \times 1 \), while \( y^+_t \) does not depend on \( x_t \) and has dimension \( (p-d) \times 1 \). Such a
transformation can be done using, for instance, the projection matrices
\( A^+_t = (Z^t H^{-}_t Z_t)^{-1} Z^t H^{-}_t \) and
\( A^*_t = L_t H^{-}_t (I_p - Z_t A^*_t) \), where \( L_t \) is chosen such that \( A^*_t \) has full row rank and \( H^- \) is
the generalized inverse of \( H \). Since \( A^*_t Z_t = I_p \) and \( A^+_t Z_t = 0 \), the observation equation can be
transformed into

\[
\begin{bmatrix} y^*_t \\ y^+_t \end{bmatrix} := \begin{bmatrix} A^*_t \\ A^+_t \end{bmatrix} y_t = \begin{bmatrix} d^*_t \\ d^+_t \end{bmatrix} + \begin{bmatrix} x_t \\ 0 \end{bmatrix} + \begin{bmatrix} \varepsilon^*_t \\ \varepsilon^+_t \end{bmatrix}, \tag{22}
\]

with \( y^*_t = A^*_t y_t \), \( y^+_t = A^+_t y_t \), \( \varepsilon^*_t = A^*_t \varepsilon_t \), \( \varepsilon^+_t = A^+_t \varepsilon_t \), \( d^*_t = A^*_t d_t \) and \( d^+_t = A^+_t d_t \). Using
\( H^- H^- = H^- \), we have

\[
\text{Var}(\varepsilon^*_t) = A^*_t H_t A'^* = (Z^t H^{-}_t Z_t)^{-1} =: H^*_t, \\
\text{Var}(\varepsilon^+_t) = A^+_t H_t A'^+_t =: H^+_t, \\
\text{Cov}(\varepsilon^*_t, \varepsilon^+_t) = A^*_t H_t A'^+_t = A^*_t H_t (I_p - A'^*_t Z_t) H^{-}_t L' \\
= A^*_t H_t (Z^t H^{-}_t Z_t)^{-1} Z^t H^{-}_t L' = A^*_t L' - A^*_t L' = 0.
\]

In the preceding display, it has been assumed that \( \text{rank}(Z^t H^{-}_t Z_t) = d \); this is not very
restrictive, given that the dimension \( d \) of the state vector will typically be much smaller than
the dimension \( p \) of the observation vector. We also require that the matrix \( A_t = [A^*_t, A^+_t]' \) is
non-singular, such that the transformation \( A_t y_t \) does not lead to a loss of information.

The representation \( \text{[22]} \) shows that all information about the state vector \( x_t \) is contained in
the observation equation for \( y^*_t \); thus we may ignore the second equation with \( y^+_t \) and focus on
the collapsed state space model:

\[
\begin{align*}
y^*_t &= d^*_t + x_t + \varepsilon^*_t, \\
x_{t+1} &= c_t + T x_t + \eta_{t+1},
\end{align*} \tag{23}
\]

\[
\text{Var}(\varepsilon^*_t | \mathcal{F}_t) = H^*_t, \\
\text{Var}(\varepsilon^*_t | \mathcal{F}_t) = H^+_t, \\
\text{Var}(\eta_{t+1} | \mathcal{F}_t) = Q_t(x_t). \tag{24}
\]

Let us emphasize again that the collapsing transformation into a lower dimensional state
space form is also valid for the Moore-Penrose inverse covariance matrix \( H^- \). Therefore, we
can collapse a high-dimensional data vector into a lower-dimensional vector even when the
covariance system matrix of disturbances is (near-) singular.

The logarithm of the Gaussian likelihood function of the data vector \( Y_T = (y^*_1, \ldots, y^*_T)' \) is

\[
l(Y_T; \theta) = \sum_{t=1}^{T} \log p_\theta(y_t | Y_{t-1}),
\]

16
where \( p_\theta(y_t|y_{t-1}) \) is the (misspecified) Gaussian distribution of \( y_t \) conditional on \( y_{t-1} \), which can be evaluated via the prediction error decomposition based on the original state space representation (19)-(20). Given the assumption of a full rank transformation matrix \( |A_t| \), the collapsed transformation allows to decompose the log-likelihood function \( l(Y_T; \theta) \) into three parts to ease computation:

\[
l(Y_T; \theta) = l(Y_T^+; \theta) + l(Y_T^-; \theta) + \sum_{t=1}^{T} \log |A_t|,
\]

where \( Y_T^+ \) and \( Y_T^- \) are stacked vectors of \( y_t^* \) and \( y_t^+ \) over \( t = 1, \ldots, T \), respectively.

The first term in \((25)\) is the quasi-loglikelihood evaluated by the Kalman filter applied to the collapsed state space system (23)-(24):

\[
l(Y_T^+; \theta) = -\frac{d}{2} \log 2\pi - \frac{1}{2} \sum_{t=1}^{T} \log |F_t^+| - \frac{1}{2} \sum_{t=1}^{T} v_t^* F_t^+ v_t^* - 1,
\]

where \( v_t^* \) are the prediction errors and \( F_t^+ \) are their mean-square error (MSE) matrices from the Kalman filter.

Since \( y_t^+ \) does not depend on the state vector \( a_t \) and \( |H_t^+| = 1 \) may be imposed without loss of generality, see \cite{Jungbacker2015}, the second term is given by

\[
l(Y_T^-; \theta) = -\frac{(p-d)T}{2} \log 2\pi - \frac{1}{2} \sum_{t=1}^{T} (y_t^- - d_t^-)'(H_t^-)^{-1}(y_t^- - d_t^-).
\]

Fortunately, the last term in the expression above can be calculated without construction of the matrix \( A_t^+ \):

\[
(y_t^+ - d_t^+)'(H_t^+)^{-1}(y_t^+ - d_t^+)(y_t^+ - d_t^-) = (y_t - d_t)'A_t^+(A_t^+ H_t A_t^+)^{-1}A_t^+(y_t - d_t)
\]

\[
= (y_t - d_t)'J_t^+ H_t^-(y_t - d_t)
\]

\[
= (y_t - d_t)' J_t^+ H_t^- J_t' (y_t - d_t)
\]

\[
= (y_t - d_t)' M_Z H_t^- M_Z (y_t - d_t)
\]

\[
= \epsilon_t H_t^- \epsilon_t,
\]

where \( M_Z = I - Z_t(Z_t' H_t^- Z_t)^{-1} Z_t' H_t^- = I - Z_t A_t^+ J_t^+ = A_t^+(A_t^+ H_t A_t^+)^{-1}A_t^+ H_t \) and \( \epsilon_t = M_Z (y_t - d_t) \), that is, these are the generalized least squares (GLS) residuals from the observation vector \( y_t \) with the covariate matrix \( Z_t \) and variance matrix \( H_t \). For derivation details\(^8\) see \cite{Jungbacker2015}.

Finally, the third term in \((25)\), \( |A_t| \), can be found from the relation

\[
|A_t|^2 \cdot |H_t| = |A_t H_t A_t^+| = |H_t^+| \cdot |H_t^+| = |H_t^+|, \tag{26}
\]

which follows from the fact that the covariance matrix \( A_t H_t A_t^+ \) is block diagonal given the uncorrelated error terms \( \epsilon_t^* \) and \( \epsilon_t^+ \) and using again \( |H_t^+| = 1 \).

\(^8\)The derivation in \cite{Jungbacker2015} is based on the invertible covariance matrix \( H_t \), but the same result and the same derivation are valid when using the pseudo-inverse matrix \( H_t^- \).
Given the measurement error structure as implied by Proposition 1, the single scale parameter \( \sigma^2 \) of the covariance matrix can be factored out as \( H_t = \sigma^2 \cdot \tilde{H}_t \). The matrix \( \tilde{H}_t \) has a block-diagonal structure; although its blocks depend on the state vector and parameters via the theoretical BSIV \( \kappa_t(\tau, m) \) and vega \( \nu_t(\tau, m) \), we estimate these quantities directly from the data, hence they are not updated as we optimize over \( \theta \). Thus, we have from (26) that

\[
\log |A_t| = \frac{1}{2} \left( \log |H^*_t| - \log |H_t| \right)
\]

\[
= \frac{1}{2} \left( \log |H^*_t| - \log \sigma^{2p} - \log |\tilde{H}_t| \right)
\]

\[
\propto \frac{1}{2} \log |H^*_t| - p \log \sigma_\kappa.
\]

Therefore, the log-likelihood (25) is proportional to

\[
l(Y_T; \theta) \propto \frac{1}{2} \sum_{t=1}^{T} \left( -\log |F^*_t| - v_t^r F_t^{-1} v_t^* - \epsilon_t^\prime H_t^\prime \epsilon_t + \log |H^*_t| \right) - pT \log \sigma_\kappa. \tag{27}
\]

Note that the inversions and determinants of the matrices \( F_t^* \) and \( H_t^* \) can be computed efficiently since they have small dimensions \( d \times d \). This eases maximization of the log-likelihood function (27) substantially.

The quasi maximum-likelihood parameter estimates \( \hat{\theta} \) are obtained by maximizing (27) over the model parameter space \( \Theta \). Its asymptotic properties are analogous to QML estimation based on the (modified) Kalman filter, as discussed at the beginning of this sub-section. In cases where the conditional covariance matrix \( Q_t \) does not depend on the latent state vector \( x_t \), and the latent state process \( x_t \) is stationary, QML based on the Kalman filter will yield consistent and asymptotically normal estimators. When \( Q_t \) is affine in \( x_t \), then QML based on the modified Kalman filter appears to have comparable properties in Monte Carlo simulations, but no formal consistency proof is available.

4 Monte Carlo Study

In this section we study the finite-sample performance of our estimation procedure. In particular, we consider two AJD specifications: a one-factor and two-factors option pricing models.

Before we turn to the Monte Carlo, we note that our developed estimation and filtering approach utilizes the information from the option prices, but is agnostic about the equity risk premia. The reason is that the measurement equation is a portfolio of options rather than the underlying asset. On the other hand, since the transition equation in the state space representation reflects the dynamics of the latent components, it is, in general, possible to learn the risk premia associated with this latent process (for instance, the volatility risk premia). However, our simulation results suggest that the \( Q \)-information in the option prices largely dominates the \( P \)-information making the identification of the volatility risk premia hardly possible. Therefore, in what follows, we assume no volatility (or state related) risk premia, that is, the latent components has the same dynamic under the both probability measures.
4.1 SVCDEJ

As a starting point, we illustrate the developed estimation approach based on the modification of the widely used ‘double-jump’ stochastic volatility model of Duffie et al. (2000). The modification is due to the double-exponential jump sizes in returns as in Kou (2002) and Andersen et al. (2015), and stochastic jump intensity that is multiple of stochastic variance as in Pan (2002). We label this specification as ‘SVCDEJ’ for stochastic volatility model with co-jumps in volatility and double-exponential jumps in returns.

In particular, we assume the following data-generating process for the log forward price under the both $\mathbb{P}$ and $\mathbb{Q}$ probability measures:

$$
\begin{align*}
    d \log F_t &= \left( -\frac{1}{2} v_t - \mu \lambda_t \right) dt + \sqrt{v_t} dW_{1,t} + Z_t dN_t, \\
    dv_t &= \kappa (\bar{v} - v_t) dt + \sigma \sqrt{v_t} dW_{2,t} + Z_t^v 1_{\{Z_t < 0\}} dN_t,
\end{align*}
$$

where two Brownian motions $W_1$ and $W_2$ are assumed to be correlated with the coefficient $\rho$ and $N_t$ is the Poisson jump process with jump intensity which is proportional to the stochastic variance $\lambda_t = \delta v_t$. We further assume that $Z_t$ is the double-exponentially distributed jump sizes in returns with the pdf

$$
f_Z(x) = p^+ \frac{1}{\eta^+} e^{-\frac{1}{\eta^+} x} 1_{\{x \geq 0\}} + p^- \frac{1}{\eta^-} e^{-\frac{1}{\eta^-} x} 1_{\{x < 0\}},
$$

where $p^+$ and $p^-$ are probability of positive and negative jumps, respectively, and $\eta^+$ and $\eta^-$ are corresponding conditional means of the jump sizes. We assume that all of these parameters are positive, $p^+ + p^- = 1$ and $\eta^+ < 1$. Given the jump size distributions, the expected relative jump size in returns is

$$
\mu := \mathbb{E}[e^Z - 1] = \frac{p^+}{1 - \eta^+} + \frac{p^-}{1 + \eta^-} - 1.
$$

Finally, we allow the volatility to co-jump only with negative jumps sizes in returns with exponentially distributed jump sizes with mean $\mu_v$. We assume no risk premia associated with the volatility, that is, the volatility process is the same under the physical and pricing probability measures.

The model in (28)-(29) belongs to the AJD class and exhibits all important ingredients for the option-pricing models: stochastic volatility, jump components in returns and volatility, time-varying jump intensity and self-excitation feature. Furthermore, this specification assumes a double-exponential jump distribution for jump sizes in returns, which has been recently advocated in the literature (see, e.g., Kou 2002, Andersen et al. 2015 and Bardgett et al. 2019).

The discounted marginal CCF of the log forward prices in the SVCDEJ model is given by

$$
\phi_t(u, \tau) = \mathbb{E}[e^{iu X_t} | F_t] = e^{\alpha(u, \tau) + \beta_1(u, \tau) \log F_t + \beta_2(u, \tau)v_t},
$$

where $u \in \mathbb{R}$ is an argument and $\alpha(u, \tau)$ and $\beta(u, \tau)$ are solutions to the complex-valued ODE system in time:

$$
\begin{cases}
    \dot{\beta}_1(s) &= 0, \\
    \dot{\beta}_2(s) &= -\left( \frac{1}{2} + \mu \delta \right) \beta_1(s) - \kappa \beta_2(s) + \frac{1}{2} \beta_1(s) + \rho \sigma_v \beta_1(s) \beta_2(s) + \frac{1}{2} \sigma^2 \beta_2^2(s) + \delta (\chi(\beta_1, \beta_2) - 1), \\
    \dot{\alpha}(s) &= \kappa v \beta_2(s) - \tau,
\end{cases}
$$
with initial conditions $\beta_1(0) = iu$, $\beta_2(0) = 0$ and $\alpha(0) = 0$. Here the ‘jump transform’ is

$$\chi(\beta_1, \beta_2) = \frac{p^+}{1 - \beta_1 \eta^+} + \frac{p^-}{(1 + \beta_1 \eta^-)(1 - \beta_2 \mu_v)}.$$ 

The CCF of the log price is used to price options. For the state space representation, we turn it into the CCF of the log returns as described in Section 2.3. Then, the linear relation between the log of the option-spanned CCF and the state vector is given by

$$\log \hat{\phi}_t(u, \tau) = \alpha(u, \tau) + \beta_2(u, \tau) v_t + \xi_t(u, \tau), \quad u \in \mathbb{R},$$

where $\hat{\phi}_t(u, \tau)$ is the option-implied CCF, $\tau > 0$ is the time-to-maturity of available options and $\xi_t(u, \tau)$ is the measurement error term due to observation and approximation errors in the option-spanned CCF. We use this linear relation to construct the measurement equation as discussed in Section 3.1.

Following Appendix C, the conditional mean and variance of the latent stochastic volatility process are given by

$$E[v_{t+1} | F_t] = e^{g_1 \Delta t} v_t + g_0 \frac{g_1}{g_1} (e^{g_1 \Delta t} - 1),$$

$$\text{Var}(v_{t+1} | F_t) = -\sigma^2 + 2p^- \delta \mu_v \frac{2g_1 (e^{g_1 \Delta t} - e^{2g_1 \Delta t}) v_t - g_0 (1 - e^{g_1 \Delta t})^2}{2g_1^2},$$

with $g_0 = \kappa \bar{v}$ and $g_1 = -\kappa + p^- \delta \mu_v$. Equations (31) and (32) are then used to define the state updating equation:

$$v_{t+1} = c + T v_t + \eta_{t+1}$$

where $c = \frac{g_0}{g_1} (e^{g_1 \Delta t} - 1), \quad T = e^{g_1 \Delta t}$ and $\text{Var}(\eta_{t+1} | F_t) = \text{Var}(v_{t+1} | F_t) =: Q_t(v_t)$. We also impose the Feller condition $2\kappa \bar{v} > \sigma^2$ and the covariance stationary condition $\kappa > p^- \delta \mu_v$.

The model specification has nine parameters of interest and a single parameter that characterizes the observation errors. We note that the parameter $\delta$ often enters as a multiple of $p^-$, which can possibly cause identification issue in the estimation procedure. Therefore, to avoid the identification issues we fix the probability of positive jumps to be $p^- = 0.7$. This is consistent with findings in Ait-Sahalia et al. (2015) and our empirical results for the unrestricted model.

In the simulation exercise we use $T = 500$ time points with $\Delta t = 1/250$. The time-series of the log prices and true spot volatilities are simulated using the Euler scheme from the specification (28)-(29). The options data are generated using the COS method of Fang and Oosterlee (2008) based on the CCF, specified in (30). The model parameters in the simulation are indicated in Table 1 along with the Monte Carlo results. The initial values are set to $F_0 = 100$ and $v_0 = 0.015$.

In the simulation exercise we consider three tenors for options equal to 10, 30 and 60 days. For each tenor we simulate a finite number of options with log-moneyness between $m = -10 \cdot \sigma_{ATM, \tau} \sqrt{\tau}$ and $m = 4 \cdot \sigma_{ATM, \tau} \sqrt{\tau}$, where $\sigma_{ATM, \tau}$ is the BSIV of the ATM option with time-to-maturity $\tau$. Furthermore, the strikes are generated equidistantly with $\Delta K = 0.01 \cdot F_t$. Finally,
we distort the options data by adding the observation errors into the option prices for each tenor \( \tau \) and each log-moneyness level \( m \) as specified in Assumption 2, that is,

\[
\hat{O}_t(\tau, m) = O_t(\tau, m) + \sigma_\xi \cdot \kappa_t(\tau, m) \nu_t(\tau, m) \cdot \epsilon
\]

where \( \epsilon \) is an i.i.d. standard normal random variable and \( \sigma_\xi = 0.02 \). The distorted option prices are then interpolated using the cubic spline and linearly extrapolated in total variance as discussed in Appendix D.

The covariance matrix of the errors in the measurement equation is calculated as given by equation (21). To calculate the pseudo-inverse of the \( n \times n \) covariance matrix \( \hat{H}_{t,i} \) for each of the maturities \( i = 1, \ldots, k \), we set the following level of the threshold for the singular values:

\[
tol := \bar{s} \cdot n \cdot \max_j s_j
\]

with \( \bar{s} = 10^{-7} \) and where \( s_j \) are all singular values of \( \hat{H}_{t,i} \). We also consider robustness to the choice of \( \bar{s} \).

Table 1 provides the Monte Carlo results for the SVCDEJ model for six different ranges of the argument sets \( \mathcal{U} \). The results are in general show a good finite performance of the QMLE. We notice that for smaller ranges of the arguments of the CCF, the estimates exhibit biases for some model parameters. This is expected since the larger ranges provide larger information on which we build the filtering and parameter estimation procedures. On the other hand, we also notice that the variance of some parameter estimates starts increasing for a very large range of arguments \( (u = 1, \ldots, 30) \). This is likely due to an increased variance in the CCF approximation for large arguments \( u \).

To explore the robustness to the choice of the truncation level in the pseudo-inverse of the covariance matrix, we also consider another values for \( \bar{s} \). In particular, we run \( N = 300 \) simulations for each level of \( \bar{s} \) with the same parameters as in Table 1 and construct the mean root square percentage error (MRSPE) metrics, defined as \( \frac{1}{N} \sum_{i=1}^{N} \left| \frac{\hat{\theta}_i - \theta_0}{\theta_0} \right| \). Figure 1 plots the MRSPE for different levels of \( \bar{s} \) and three different ranges of arguments. As we can see, the levels \( \bar{s} \) in between \( 10^{-7} \) and \( 10^{-6} \) yield the smallest MRSPE. In the following simulations and empirical part we therefore set \( \bar{s} = 10^{-7} \).

We end this subsection by noting that we have also performed simulation exercises for some other alternative one-factor specifications. In Appendix E, we include the simulation results for the SVCJ model with Gaussian jump size distribution and the model with two separate for positive and negative jumps counting processes. The former shows a very good finite sample performance, while the latter, a richer specification, shows reasonable results, reaching the identification limits.

### 4.2 SVCDEJ with external factors

Now we extend the one-factor specification by adding an external factor. This modification can be seen as a two-factor specification, but we will assume that the second factor is observable. The motivation comes from the fact that in some situations we might have an understanding

</table>

Note: This table provides Monte Carlo simulation results for the SVCDEJ model. Six different settings with different range of the arguments are considered. We use $T = 500$ time points with $\Delta t = 1/250$. The initial values are set to $F_0 = 100$ and $v_0 = 0.015$. The threshold for singular values is set to $\bar{s} = 10^{-7}$. The probability of negative jumps is fixed to $p^- = 0.7$. 

22
of possible drivers of the risks in the market. Therefore, we would like to embed and quantify the impact of an exogenous variables to the model’s risk.

In particular, next to the stochastic volatility component we introduce the exogenous factor \( h_t \), which affects the intensity of jumps and the diffusive component. The model reads as follows:

\[
\begin{align*}
    d \log F_t &= \left( -\frac{1}{2} V_t - \mu \lambda_t \right) dt + \sqrt{v_t} dW_{1,t} + q \sqrt{h_t} dW_{3,t} + Z_t dN_t, \\
    dv_t &= \kappa (\bar{v} - v_t) dt + \sigma \sqrt{v_t} dW_{2,t} + Z_t^v 1_{\{Z_t < 0\}} dN_t, \\
    dh_t &= \kappa (\bar{h} - h_t) dt + \sigma_h \sqrt{h_t} dW_{4,t},
\end{align*}
\]

where \( V_t = v_t + q^2 h_t \) is the total diffusive variance of the process and the intensity processes \( \lambda \) is now also loaded on the process \( h_t \), that is, \( \lambda_t = \delta v_t + \gamma h_t \). We assume that \( W_{3,t} \) and \( W_{4,t} \) are independent Brownian motions. Therefore, the process \( h_t \) is exogenous process to the SVCDEJ dynamics, meaning that the dynamics of \( y_t \) and \( v_t \) do not affect the dynamics of \( h_t \). In turn, the exogenous factor \( h_t \) affects the intensity of jumps and the diffusive component of the log return dynamics. This is similar specification to two-factor model in Andersen et al. (2015), in which they have short- and long-term stochastic volatility components. However, we further assume that the exogenous process \( h_t \) is observable, although its parameters are unknown.

In the Monte Carlo simulation we consider two possible estimation approaches. In the first approach, we assume the correct specification of the dynamics for \( h_t \) with known true parameters \( \kappa_h, \bar{h} \) and \( \sigma_h \). In practice, these parameters can be pre-estimated given the observed path of the exogenous process. In the second approach we estimate the misspecified model, in which the contribution of \( h_t \) is constant throughout the maturity of an option. In other words, in this case we ignore the dynamics of \( h_t \) when pricing options, but \( h_t \) still affects the level of intensity and of total variance. The motivation is that when the exogenous process is persistent and smooth relative to \( v_t \), its dynamics can be neglected when pricing options with short expiration periods. Moreover, the true parametric specification for an exogenous variable is likely unknown.
in practice. However, if its dynamics is persistent and smooth, we can find its affect on option prices via this specification. Therefore, in the Monte Carlo experiment, we simulate \( h_t \) with lower mean-reversion rate than in \( v_t \), mimicking what we will use in the empirical application.

The Monte Carlo setting for the SVCDEJ model with external factor is the same as in the SVCDEJ specification. The parameters of the external factor are set to be \( \kappa_h = 1, \, \bar{h} = 1 \) and \( \sigma_h = 0.1 \). The simulation results are provided in Table 2. The parameters of the SVCDEJ model exhibit similar performance in the both estimation settings. Importantly, the parameters related to the external factors \( \gamma \) and \( q \) also show similar performance in the misspecified setting as in the correctly specified model. We emphasize that the latter is achieved due to simulating relatively smooth and persistent exogenous process \( h_t \) and using short-dated options in the estimation procedure.

Note: This table provides Monte Carlo simulation results for the SVCDEJ model with exogenous factor. We use \( T = 500 \) time points with \( \Delta t = 1/250 \). The range for the arguments is set to \( u = 1, \ldots, 20 \) and the threshold \( \tilde{s} = 10^{-7} \). The initial values are set to \( F_0 = 100 \) and \( v_0 = 0.015 \). The probability of negative jumps is fixed to \( p^- = 0.7 \). The parameters of the external factor are set to be \( \kappa_h = 1, \, \bar{h} = 1 \) and \( \sigma_h = 0.1 \).

5 Data

This section details the data and data selection process we use in our empirical application. Since our estimation procedure utilizes the option-implied CCFs, we also pay careful attention in this section to the construction of these characteristics.

5.1 Data description

In this paper we use options data on the S&P 500 stock market index obtained from the Chicago Board Options Exchange (CBOE). We focus on the period from May 1, 2017 to April 1, 2021, that covers the turbulent period in the stock market due to the Covid-19 pandemic. The CBOE provides end-of-day option quotes and a snapshot at 3:45 pm ET, 15 minutes prior
the market closure. We use the latter to calculate mid-quotes since it is considered to be a more accurate representation of market liquidity than the former. The data contain both the ‘standard’ AM-settled SPX options and Weeklys and End-of-Months PM-settled SPXW products. The settlement value for the SPX options is based on the open level of the S&P 500 index on settlement day, while for the SPXW options it is based on the closing prices of the index.

</table>

Note: Descriptive statistics for filtered option data on S&P 500 stock market index. The sample contains daily option data from 1 May 2017 to 1 April 2021. Observations are bucketed into six categories based on the time-to-maturity, $\tau$, and into five categories with respect to the moneyness level, defined as strike-to-forward ratio $k = K/F$.

Given that we need a reliable and wide coverage of option prices for each tenor, we use a fairly generous set of filters. In particular, we retain option observations that satisfy the following criteria: (i) bid price is strictly positive and ask-to-bid ratio is less than 10; (ii) the maturity is larger than or equal to 2 calendar days, but less than or equal to 365 calendar days; (iii) it is not an early-closure day. The first criterion filters out illiquid observations and the second one limits our consideration in terms of options’ maturity. The third criterion rules out shortened trading sessions, which in total constitute 10 days in our sample.
For each tenor we determine the moneyness based on the forward index level, $F_t(\tau)$. For that, we use the put-call parity to calculate the forward price for close to at-the-money (ATM) options. Specifically, we use up to 5 option pairs with the smallest absolute difference between the call and put prices. The median of their forward-implied prices is taken as the forward index level for the corresponding tenor. The risk-free rates are obtained by interpolating the LIBOR rates to a particular tenor. Finally, given the calculated forward prices and moneyness levels, we retain only out-of-the-money (OTM) options for further exploitation. The descriptive statistics of the S&P 500 index options data sample is provided in Table 3. We observe that the largest portion of trading volume is due to trades of OTM contracts and options with time-to-maturity less than 60 calendar days. Figure 2 plots frequency of tenors up to 70 calendar days.

5.2 CCF-spanning option portfolios

The construction of the CCF-spanning option portfolios requires reliable option slices with wide coverage of strikes. Given that most of the trading volume is concentrated in the option contracts with time-to-maturity less than 60 days, in our empirical analysis we use several short-dated options with expiration period no more than 2 months. In particular, on each trading day we keep six tenors closest to 8, 15, 22, 29, 36 and 61 days from the left with the largest trading volume and number of quoted OTM option contracts. Specifically, starting with option slices closest to the indicated tenors, we compare them with every next further distant from the left option slice and prefer the next one if it has larger trading volume and larger number of

---

9The first five of these tenors are the most representative in the sample. See Figure 2

Note: Descriptive statistics for the selected sample data of options on S&P 500 stock market index. The sample contains daily option data from 1 May 2017 to 1 April 2021. For each trading day, we select six option tenors closest to 8, 15, 22, 29, 36 and 61 days from the left and with the largest trading volume and number of quoted OTM option contracts. The table provides the descriptive statistics for each of the six tenors over the sample.

quoted contracts for OTM options. Table 4 provides the descriptive statistics for each of the six selected tenors over the considered time span. We notice the wide coverage of strikes since the average minimum put and call prices are close to the tick size of $0.05, especially for very short-dated options. We also notice that in the selected option sample, each option slice at each trading day contains at least 55 different quoted contracts. Therefore, no additional filters on the minimum number of contracts are imposed. In total, we have 978 trading days, with six different tenors at each of them, resulting in 1,158,059 number of contracts in the sample.

The inputs of our estimation procedure are option portfolios representing CCFs rather than BSIVs, as is common in the literature. Therefore, we pay careful attention to the construction of the option-implied CCF. As discussed in Appendix A, we use the Riemann sum approximation to obtain a computable counterpart of the CCF spanning (3). However, in order to reduce the discretization and truncation errors, we employ the interpolation-extrapolation technique that we discuss below. The importance of the interpolation-extrapolation scheme is also discussed in Appendix A.

For each trading day and for each tenor, we interpolate option prices using cubic splines. We interpolate option data, expressed in terms of their total implied variance, defined as \( v(m, \tau) = \kappa^2(m, \tau) \cdot \tau \), where \( \kappa(m, \tau) \) is the Black-Scholes implied volatility for an option with log-moneyness \( m \) and tenor \( \tau \). This is similar to interpolating on the implied volatility domain, but it will provide us further advantages when we go to the extrapolation scheme.

The cubic splines provide a great tool for the interpolation of options data and are commonly used in the literature, see, for instance, [Jiang and Tian (2007), Malz (2014)] among many others. Furthermore, they are also used as an approximation method, that allows to smooth out noise in the data; see, for instance, [Bliss and Panigirtzoglou (2002), Fengler (2009)]. For the latter it is common to penalize the squared second derivative of the spline. This, however, might lose flexibility of a spline leading to larger approximation errors, especially for short-dated options, which are of great importance in our analysis. In this paper, we use the standard cubic spline, but instead of providing all data as knot points, we explicitly specify which data points shall be
used as knots for spline interpolation. This allows us to interpolate in some domains and smooth out in others, taking the best out of the interpolation and approximation spline schemes.

In fact, close to ATM options are more liquid than very deep OTM counterparts. Thus, intuitively, information in these options is more reliable, and we would not like to distort it, by imposing smoothing constraints. Very deep OTM options, on the other hand, may be quite illiquid. Furthermore, the tick size for deep OTM options becomes larger relative to their value. This might lead to observing a sequence of the same midpoint quote prices in the data. Figure 3 provides an example of such ‘flat’ prices for put options, visible on the right panel for very deep OTM options. These prices clearly violate arbitrage-free assumptions. However, throwing them away would reduce available information, needed to extract CCF. Therefore, instead of eliminating ‘flat’ prices, we will just not include them as knot points in our spline interpolation scheme. In other words, we would not require the spline function to go through all data points for deep OTM options, but rather let it approximate information in them.

More formally, first, we include the closest to ATM put option, $m_1$, to the knot sequence and then iteratively include put options to the left $m_i$ for $i = 2, \ldots, n - 1$ such that all following conditions are satisfied: (i) $P(m_i) < P(m_{i-1})$ and $C(m_i) > C(m_{i-1})$; (ii) $P(m_{i+1}) < P(m_i)$ and $C(m_{i+1}) > C(m_i)$; (iii) daily trading volume for $P(m_i)$ is larger than one. The first two criteria check for arbitrage conditions. The third one filters out possible stale prices from being a knot point. Similar mirrored conditions are applied to OTM call prices. Such a constructed knot sequence will likely contain more closer to ATM options and less deep OTM options, resulting in more interpolation in the former range and more approximation in the later one.

We note that we do not filter out option data that violate arbitrage conditions. Instead, we do not include these points into the knot sequence, thus we do not require the spline to go

---

10 These prices are not completely uninformative, it is just that the tick size distorts information in these prices.
11 Recall that we interpolate/approximate data on the total implied variance domain, not in terms of implied volatility, option prices or log prices as illustrated in Figure 3.
exactly through these points. Furthermore, another reason is that we use the option-implied CCFs rather than option prices themselves as inputs in our estimation procedure. Similarly, the CBOE does not impose any arbitrage filters in the calculation of the VIX index, except eliminating zero-bid quotes (CBOE, 2015). Figure 3 provides an example for interpolation-extrapolation scheme for option slice traded on April 1, 2020 with 15 days-to-maturity.

Truncation errors are more challenging to address than the discretization errors, since one needs to make assumptions on the dynamics of option prices (either in dollar or volatility terms) beyond the observable range of strikes. On the other hand, as the OTM option prices decrease with $|m|$, the impact of the truncation error is expected to be small for very liquid options (such as index options) that cover a wide range of strike prices. However, the truncation might deteriorate the CCF approximation even for small argument values. This is especially might be a serious issue after a sudden market movements, since options with smaller (or larger) strikes might simply not be issued immediately to cover a new range of strikes.

It is common in the literature to use the flat extrapolation; see as example again Bliss and Panigirtzoglou (2002), Jiang and Tian (2005), Malz (2014). Under the flat extrapolation scheme the implied volatility is simply set to be equal to the volatility of the observable extreme-strike options, that is $\kappa(m_l, \tau)$ for the left hand-side and $\kappa(m_u, \tau)$ for the right hand-side of volatility smile. Very simple to implement, this approach allows to significantly reduce the truncation error. However, the main caveat of the flat extrapolation is that it presumes the Black-Scholes assumptions beyond the observable range of strikes. In other words, it assumes the log-normal distribution of the underlying asset in the tails. From the RND perspective, it means that a shape of the lognormal distribution is used beyond the highest and lowest available strike prices.

Therefore, in this paper, we extrapolate the total implied variances $v(m, \tau)$ linearly in the log-moneyness $m$ beyond the observable range of strikes. This particular linear parametrization is motivated by the asymptotic result of Lee (2004), who established the behavior of the implied volatility smile as strikes tend to infinity. Another example of the parametrization that satisfies Lee’s asymptotic result is the SVI model, commonly used among practitioners (Gatheral & Jacquier, 2014). However, it is well known that the SVI might not fit well the short dated options’ shapes. Thus, we use more flexible cubic spline for interpolation within the observable range of strikes, as detailed above, and, similar to SVI, extrapolate implied variance linearly in the log-moneyness.

Given the fitted cubic spline on the implied variance domain, we evaluate the spline derivatives at the moneyness levels, corresponding to the second smallest OTM quote price from the left (that is, for put options) and from the right (that is, for call options). We use the second smallest prices to eliminate the boundary effect of the spline. After obtaining the derivatives, we extrapolate the wings linearly in the total variance after checking the arbitrage-free conditions. We provide greater details of the extrapolation scheme together with arbitrage-free conditions on the extrapolation slopes in Appendix D.

Finally, the calculation of the option-implied CCF uses the Riemann sum approximation as discussed in Appendix A applied to the result of the interpolation-extrapolation scheme. The construction is conducted for each day and for each maturity separately. In particular,
for equation A.2 we set $\Delta m = 0.0001$ with sufficiently wide range of log-moneyness between $m_l = -6$ and $m_u = 2$.

To conclude this section we emphasize again that the option prices or a monotonic transformation thereof are not used as inputs in our developed estimation procedure as is common in many existing approaches. Instead, we use the option portfolios that replicate the CCF of the log returns. Furthermore, unlike in many other papers, our option dataset is daily and utilizes the information from the short-dated options with maturities between two days and two months.

6 Empirical Applications

After having constructed the dataset of the option-implied CCF for the S&P 500 index options, we now turn to the empirical application of our estimation approach.

6.1 SVCDEJ

We start with estimating the SVCDEJ model, specified in Section 4.1, equations (28)-(29). Table 5 provides the results of the parameter estimates for the SVCDEJ model based on the range of arguments $u = 1, \ldots, 20$ and $s = 10^{-7}$. To avoid identification issues we with the parameter $p^{-} = -0.7$ following results in Aït-Sahalia et al. (2015). The standard errors are calculated using the sandwich form covariance matrix.

</tbody>
</table>

The parameter estimates in Table 5 are consistent with the literature and intuitive. For instance, Andersen et al. (2015) found the mean jump sizes to be 1.71% and -5.33% for positive and negative jumps in their three-factor model specification. They, however, use only the Wednesday options with different time period from 1996 to 2010.

We note that the leverage parameter $\varrho$ comes very close to the boundary. Although the literature suggests that the leverage is negative and low, almost perfectly correlated diffusive parts in the return and volatility are very unlikely. This might be possibly due to exploitation of the short-dated options that typically exhibit steeper implied volatility slopes. Andersen et al. (2017) also found the correlation to be close to -1 in their dataset dominated by the option contracts with maturities less than 2 months.

Figure 4 plots the square root of the filtered variance $\hat{v}_{t+1|t}$ given the parameter estimates of the SVCDEJ model. As expected, the filtered volatility exhibits a relatively stable volatility regime prior to 2020 and jumps up in March 2020 at the beginning of the Covid-19 pandemic.
Figure 4: SVCDEJ filtered volatility

Note: This figure plots the filtered volatility (square root of the filtered state $\hat{x}_{t+1|t}$) given the parameter estimates of the SVCDEJ model. The Kalman filter recursions and the model parameter estimates are used for the filtering.

6.2 SVCDEJ with external factor

Now we turn to the specification with embedded external factors. The motivation comes from the fact that in some situations we might have an understanding of possible drivers of the risks in the market, and thus, we would like to quantify it.

An example is the recent Covid-19 crisis. The Covid-19 pandemic has dramatically affected our lives. It has also had a tremendous impact on the world’s economy and financial markets. The beginning of the pandemic was especially associated with a spike in uncertainty. This uncertainty surrounded many aspects of the beginning of the Covid-19 pandemic: the contagiousness and lethality of the virus, the time needed to develop vaccines, the effectiveness of measures, the work-from-home policies, travel bans and etc.

In this paper we analyse the impact of the Covid-19 pandemic on the stock market through the lens of option prices. In particular, we consider how the spread of the virus affected the likelihood of jump events and volatility in the U.S. stock market.

Figure 7 plots the daily cases of the Covid-19 infections around the world obtained from the World Health Organization (WHO). As we can see from the figure, the reported number of daily cases does not represent well the contagiousness of the virus. Therefore, Panel (b) of Figure 7 provides the reproduction number dynamics taken from the web-site ‘Our world in Data’ and calculated as the ratio $R_t = \frac{I_t}{I_{t-7}}$, where $I_t$ is number of infected people in day $t$ and 7 is the reported serial interval for the Covid-19. The former is based on the methodology of Arroyo-Marioli et al. (2021) and is already smoothed in time. The latter is unsmoothed and

\footnote{In fact, Arroyo-Marioli et al. (2021) use the Kalman smoother.}
based on the assumption that the serial interval is 7 days, which is consistent with the recent epidemiology literature (see, e.g., Maier & Brockmann 2020, Prem et al. 2020, Flaxman et al., 2020, Arroyo-Marioli et al., 2021). We will use the latter as the reproduction number for our analysis below.

To quantify the effect of the Covid-19 pandemic on the financial market, we simply embed the reproduction numbers to the (time-varying) levels of the volatility and jump intensity processes as described in Section 4.2. In other words, given that the reproduction number is a relatively persistent process, we will treat it as a deterministic process when pricing the options. In a similar way, the risk-free rate and dividend yields are often assumed to be deterministic in the option pricing literature. This allows us to be agnostic about the parametric dynamics of the reproduction number. Furthermore, given the short-dated options in the consideration, the errors due to the deterministic assumption will likely to be negligible.

Note: this table provides the parameter estimates for the SVCDEJ model with the reproduction number as external factor. The model is estimated based on u = 1, ..., 20 and s = 10⁻⁷ with fixed p⁻ = 0.7.

Table 6 provides the results for the SVCDEJ model with the reproduction number as an exogenous factor. The results suggest that the reproduction number dynamics has no significant effect on the total volatility and the likelihood of the positive jumps. However, a unit of the reproduction number increases the intensity of negative jumps by 2.64. In other words, the

Similarly, Andersen et al. (2017) and Boswijk et al. (2021) consider approximation of the return process with ‘freezed’ spot volatility when estimating their option pricing models with short-dated options.
reproduction number partly explains the source of the negative jump intensity dynamics. Figure 6 illustrates the dynamics of the negative jump intensity with and without added effect of the reproduction number $R_t$.

Note: This table provides the parameter estimates for the SVCDEJ model with the EPU as external factor. The model is estimated based on $u = 1, \ldots, 20$ and $s = 10^{-7}$ with fixed $p^- = 0.7$.

It is also possible to investigate the contribution of some other external factors on the diffusive volatility and jump intensity. For instance, in Table 7 we provide the estimation results for the SVCDEJ model with the Economic Policy Uncertainty (EPU) index as the external factor. The EPU index, developed by Baker, Bloom, and Davis (2016), reflects the policy-related economic uncertainty based on newspaper coverage frequency. The estimation results suggest that, unlike the reproduction number, the EPU index shows no effect on the jump intensity process, but exhibits larger contribution to the diffusive volatility of the model.

7 Conclusion

In this paper, we have proposed a novel state filtering and parameter estimation procedure for option pricing models that belong to the affine jump-diffusion class. Our procedure utilizes the log of the option-implied and model-free conditional characteristic function as well as the model-implied conditional log-characteristic function, which is functionally affine in the model’s state vector. We have provided a corresponding linear state space representation for
Figure 7: EPU index and filtered diffusive volatility

Note: Panel (a) plots the EPU index of [Baker et al. (2016)]. The data is divided by 100 and one week moving average is applied. Panel (b) plots the total and filtered diffusive volatility from the estimation result of the SVCDEJ with the EPU index. The total volatility is given as \( \sqrt{v_t + q^2 h_t} \), where \( h_t \) is the external factor.

the considered class of option pricing models, which allows us to exploit suitably adapted collapsed Kalman-type filtering techniques. Our novel estimation procedure is fast and easy to implement, circumventing the typical computational burden when working with option pricing models. We have demonstrated the applicability of our procedure in two empirical illustrations that analyze S&P 500 index options and the impact of exogenous variables capturing Covid-19 reproduction and economic policy uncertainty data.
Appendix A  Conditional Characteristic Function Replication

This appendix provides further details on the CCF ‘payoff’ replication given a portfolio of option prices. As discussed in Section 2, the discounted CCF of log returns over the time horizon $\tau > 0$ can be spanned via positions in a risk-free bond and OTM options:

$$\phi_t(u, \tau) = e^{-r\tau} - (u^2 + iu) \frac{1}{F_t} \int_{\mathbb{R}} e^{(iu-1)m} \cdot O_t(\tau, m) dm, \quad u \in \mathbb{R},$$

(A.1)

where $O_t(\tau, m)$ is the price of OTM options with log-moneyness level $m = \log(K/F_t)$ and time-to-maturity $\tau$.

Figure A.1 provides an illustration of OTM option prices and corresponding spanning, option portfolio weights for simulated data from the stochastic volatility (SV) model of Heston (1993). The option portfolio weights are scaled by the factor in front of the integral in (A.1). We notice that the spanning option portfolios require both short and long positions in OTM options and the weights start oscillating for larger values of arguments $u$. Figure A.2 further provides an example of the real and imaginary parts of the integrands $e^{(iu-1)m} \cdot O_t(\tau, m)$ against the log-moneyness level $m = \log(K/F_t)$ for four different values of the arguments $u$ with fixed time-to-maturity $\tau = 30$ days. The corresponding integrals need to be calculated to replicate the CCF ‘payoff’ function.

In practice, the integral $\int_{\mathbb{R}} e^{(iu-1)m} \cdot O_t(\tau, m) dm$ in equation (3) cannot be calculated explicitly as we observe option prices only for a finite set of strikes. Nevertheless, given a set of observable option prices we can use, for instance, the Riemann sum to make a first approximation of this integral. Defining a finite sequence of log-moneyness levels that corresponds to observable options by $m := m_1 < \cdots < m_n =: \overline{m}$, this approximation of the CCF is given by

$$\phi_t(u, \tau) \approx e^{-r\tau} - (u^2 + iu) \frac{1}{F_t} \sum_{j=2}^{n} e^{(iu-1)m_j} \cdot O_t(\tau, m_j) \Delta m_j,$$

(A.2)

where $\Delta m_j = m_j - m_{j-1}$. When $\max_j \Delta m_j \to 0$ accompanied in this case by $m \to -\infty$ and $\overline{m} \to \infty$, the Riemann sum converges to the option-spanned CCF.

A similar integral approximation is at the core of the VIX index—one of the most widely used volatility indices. Like in VIX calculation, the approximation (A.2) exhibits two types of errors: truncation and discretization errors. Jiang and Tian (2005) and Jiang and Tian (2007) study the impact of these errors on the VIX index calculation and Chang et al. (2012) examines their impact on other option-implied measures of risk. The literature on risk-neutral density extraction also addresses the effect of these errors; see, for instance, Bliss and Panigirtzoglou (2002) and Malz (2014). To reduce the impact of the approximation errors, we follow this literature and use an interpolation-extrapolation scheme based on cubic splines. We provide the details of this scheme in Section 5, where we discuss the construction of the spanning option portfolios for our empirical application.

Next to the truncation and discretization errors in the option-spanned CCF in equation (A.2), approximation errors may also arise due to observation errors in option prices. That is, 

14To be precise, the VIX methodology is based on the trapezoidal rule (CBOE, 2015).
Figure A.1: OTM option prices and corresponding (scaled) option portfolio weights for the SV model of Heston (1993).

(a) OTM option prices

Note: Panel (a) of this figure plots OTM option prices for the simulated SV model of Heston (1993) against the log-
moneyness level $m = \log(K/F)$ for three different levels of maturity $\tau$. Panels (b) and (c) provide the (scaled) option
portfolio weights $e^{(n-1)m}$ to replicate the CCF for different arguments $u$ and fixed time-to-maturity $\tau = 30$ days. The
following parameters are used: $\kappa = 8$, $\sigma_v = 0.45$, $\bar{v} = 0.015$, $\rho = -0.95$, $F_0 = 100$ and $v_0 = 0.015$.

the true option prices $O_t(\tau, m)$ are not observed in the market. Instead, what we observe is their
distorted signal $\tilde{O}_t(\tau, m)$ due to e.g., bid-ask spreads, liquidity reasons, and minimum tick size.
Therefore, we also take into account the observation errors when making assumptions on the
measurement errors. In fact, as we elaborate in Appendix B, the observation errors constitute
the main source of the measurement errors in the state space representation.

Overall, the replication of the CCF ‘payoff’ uses the Riemann sum approximation based on
an interpolation-extrapolation scheme applied to the set of observable option prices. We denote
by $\tilde{\phi}_t(u, \tau)$ the computationally feasible counterpart of the option-implied CCF $\phi_t(u, \tau)$.

Figure A.2 provides an illustration of the impact of different measurement errors on the
option-implied CCF. For the illustration, we simulate option prices from the SVCJ model using
a similar setup as described in Section 4. In particular, at each time point we have a discrete
set of strikes and additive observation errors in the observed option prices. We fix the time-to-
maturity to $\tau = 10$ days, $u = 20$ and focus only on the real part of the CCF. These values are
Figure A.2: Integrands $e^{(iu-1)m} \cdot O_t(\tau, m)$ for the SV model of Heston (1993).

Note: This figure plots the real and imaginary parts of four integrands $e^{(iu-1)m} \cdot O_t(\tau, m)$ for the simulated SV model of Heston (1993) against the log-moneyness level $m = \log(K/F_t)$ for different arguments $u$ and fixed time-to-maturity $\tau = 30$ days. The following parameters are used: $\kappa = 8$, $\sigma_v = 0.45$, $\bar{v} = 0.015$, $\rho = -0.95$, $F_0 = 100$ and $\nu_0 = 0.015$.

chosen to emphasize the impact of the measurement errors. The impact of the discretization errors, for instance, is typically smaller for larger maturities and smaller argument values.

Figure A.3 (a) plots the measurement errors when we use a finite set of observed option prices $\hat{O}_t(\tau, m)$. That is, it shows the total measurement errors $\zeta_t(u, \tau)$ that aggregate the three types of errors: observation, $\zeta_t^{(1)}(u, \tau)$, truncation, $\zeta_t^{(2)}(u, \tau)$, and discretization, $\zeta_t^{(3)}(u, \tau)$, errors, formally defined in Appendix B. As we can see, the discretization and truncation errors yield a small bias in the CCF approximation. In Figure A.3 (b) we turn off the impact of observation errors, that is, we use a finite set of true option prices $O_t(\tau, m)$. Thus, the errors in the option-spanned CCF contain only the discretization and truncation errors, $\zeta_t^{(2)}(u, \tau) + \zeta_t^{(3)}(u, \tau)$. We overlay this plot with the ATM BSIV to illustrate that these errors are due to the value of options, that is, they are driven by the model’s dynamics. Figure A.3 (c) plots the sum of the first two figures, that is, $\zeta_t^{(1)}(u, \tau)$. This figure is already centered around zero.

For Figures A.3 (d) and (e), we use a cubic spline interpolation and extrapolate option prices outside of the observed range as described in Appendix D. Figure A.3 (d) plots errors in the CCF approximation when we use the true finite set of option prices, interpolated with the cubic spline to reduce the discreteness of the observed strikes. As we can see, the discretization and truncation errors are largely reduced (note the scale of the y-axis). Finally, Figure A.3 (e) illustrates the errors in the CCF approximation when options are observed with errors and the cubic spline is also applied to $\hat{O}_t(\tau, m)$. As we can see, the errors in this case are mostly coming from the observation errors. Hence, this figure largely resembles Figure A.3 (c). In other words, the interpolation-extrapolation scheme kills off the level effect that comes from the impact of the discretization and truncation errors, but not the observation errors.
Figure A.3: Impact of the three types of measurement errors: Illustration.

(a) $\zeta_t^{(1)} + \zeta_t^{(2)} + \zeta_t^{(3)}$

(b) $-\zeta_t^{(2)} - \zeta_t^{(3)}$ and ATM BSIV

(c) $\zeta_t^{(1)}$

(d) $\phi(u, \tau) - \phi(spl(O))$

(e) $\phi(u, \tau) - \phi(spl(\hat{O}))$

Note: This figure plots the impact of the three types of measurement errors on the option-implied CCF. The figures illustrate the approximation for the real part of the CCF with $\tau = 10$, $u = 20$. The same Monte Carlo simulation setup as described in Section 4 is used here to simulate data from the SVCJ model.

Appendix B Proofs

In this appendix, we elaborate on the measurement errors in the option-implied CCF given the observable option prices and provide the proof of Proposition 1.

We start by formally defining the measurement errors in the CCF approximation. Under the observation error structure specified in Assumption 2 and the CCF approximation given by equation (14), the total measurement error in the option-spanned CCF is defined by its three
components:

\[ \zeta_t^\phi(u, \tau) := \hat{\phi}_t(u, \tau) - \phi_t(u, \tau) \]

\[ = - u \sum_{j=2}^{n} e^{i(u-1)m_j} \cdot \hat{\zeta}_t(\tau, m_j) \Delta m_j + u \int_{-\infty}^{\infty} e^{i(u-1)m} \cdot O_t(\tau, m) dm \]

\[ = - u \sum_{j=2}^{n} e^{i(u-1)m_j} \cdot \hat{\zeta}_t(\tau, m_j) \Delta m_j + u \int_{-\infty}^{m_1} e^{i(u-1)m} \cdot O_t(\tau, m) dm + u \int_{m_1}^{\infty} e^{i(u-1)m} \cdot O_t(\tau, m) dm \]

\[ = - u \sum_{j=2}^{n} e^{i(u-1)m_j} \cdot \hat{\zeta}_t(\tau, m_j) \Delta m_j \]

\[ =: \zeta_t^{(1)}(u, \tau) \]

\[ + u \int_{-\infty}^{m_1} e^{i(u-1)m} \cdot O_t(\tau, m) dm + u \int_{m_1}^{\infty} e^{i(u-1)m} \cdot O_t(\tau, m) dm \]

\[ =: \zeta_t^{(2)}(u, \tau) \]

\[ + u \sum_{j=2}^{n} \int_{m_j-1}^{m_j} \left[ e^{i(u-1)m} \cdot O_t(\tau, m) - e^{i(u-1)m} \cdot O_t(\tau, m) \right] dm \]

\[ =: \zeta_t^{(3)}(u, \tau) \]

The error terms \( \zeta_t^{(1)}(u, \tau) \), \( \zeta_t^{(2)}(u, \tau) \) and \( \zeta_t^{(3)}(u, \tau) \) represent observation, truncation and discretization errors, respectively.

We now formally show that the discretization and truncation errors will be negligible in the limit. We start with the following auxiliary result for upper bounds of (normalized) option prices:

**Lemma 1** Let \( f_{t+\tau} = \frac{F_{t+\tau}}{F_t} \) be the normalized to value at time \( t \) futures price for \( \tau > 0 \). For each \( p > 0 \) we have for all \( m > 0 \) the call price bounds

\[ \frac{O_t(\tau, m)}{F_t} \leq \left( \frac{p}{p+1} \right)^p e^{-r \tau} \mathbb{E}^Q [f_{t+\tau}^p | F_t] e^{-pm}. \]  

(B.1)

For each \( q > 0 \) we have for all \( m < 0 \) the put price bounds

\[ \frac{O_t(\tau, m)}{F_t} \leq \left( \frac{q}{q+1} \right)^q e^{-r \tau} \mathbb{E}^Q [f_{t+\tau}^{-q} | F_t] e^{(1+q)m}. \]  

(B.2)

**Proof:** The result is the straightforward adaptation of Theorem 2.1 in [Lee (2004)].

Lemma 1 relates the moments of the underlying process and of its reciprocal to the bounds of the option prices. Similar to [Qin and Todorov (2019)] and [Todorov (2019)], we assume the existence of at least second order moment of the underlying process and of its reciprocal,
formulated in Assumption [3]. If higher moments exist, then we can obtain even tighter bounds for the remainder term in Proposition 1 due to [B.1] and [B.2].

The following lemma establishes the order of magnitude of the truncation and discretization errors under the joint asymptotic scheme, expressed with respect to the number of option prices \( n \) with fixed maturity. We denote the smallest and largest log-moneyness as \( \underline{m} = \min_{1 \leq j \leq n} m_j \) and \( \overline{m} = \max_{1 \leq j \leq n} m_j \), and the corresponding strike prices as \( \underline{K} \) and \( \overline{K} \).

**Lemma 2** Suppose \( \mathbb{E}^Q[|F_{i+1}^p| |\mathcal{F}_t] < \infty \) and \( \mathbb{E}^Q[|F_{i+q}^{p+1}| |\mathcal{F}_t] < \infty \) for some \( p > 0 \) and \( q > 0 \), Assumption [3(ii)] holds, and in addition \( \underline{K} \approx n^{-\alpha} \) and \( \overline{K} \approx n^{\overline{\alpha}} \) with \( \alpha > 0 \) and \( \overline{\alpha} > 0 \). Then for \( n \to \infty \) we have

\[
\zeta^{(2)}_t(u, \tau) = O_p \left( n^{-(\eta_\alpha \wedge (1+p)\overline{\alpha})} \right),
\]

and

\[
\zeta^{(3)}_t(u, \tau) = O_p \left( \frac{\log n}{n^{1+\eta_\alpha \wedge (p+1)\overline{\alpha}}} \right)
\]

for a fixed \( u \in \mathcal{U} \) and \( \tau > 0 \).

**Proof:** We start with the truncation error. For \( m_n > 0 \) and \( m_1 < 0 \) and using Lemma [1] we can bound the upper and lower truncation parts as follows:

\[
\left| \frac{1}{F_t} \int_{m_n}^{\infty} e^{(i\alpha-1)m} \cdot O_t(\tau, m) dm \right| \leq \int_{m_n}^{\infty} e^{(i\alpha-1)m} \cdot \left| \frac{O_t(\tau, m)}{F_t} \right| dm \leq \overline{C_t} e^{-(1+p)m_n},
\]

\[
\left| \frac{1}{F_t} \int_{-\infty}^{m_1} e^{(i\alpha-1)m} \cdot O_t(\tau, m) dm \right| \leq \int_{m_1}^{\infty} e^{(i\alpha-1)m} \cdot \left| \frac{O_t(\tau, m)}{F_t} \right| dm \leq \overline{P_t} e^{m_1},
\]

where \( \overline{C_t} \) and \( \overline{P_t} \) are \( \mathcal{F}_t \)-adapted random variables that do not depend on \( m \). Therefore, for \( m \to \infty \) and \( m \to \infty \) we have

\[
\zeta^{(2)}_t(u, \tau) = u \int_{m_1}^{\infty} e^{(i\alpha-1)m} \cdot O_t(\tau, m) dm + u \int_{-\infty}^{m_1} e^{(i\alpha-1)m} \cdot O_t(\tau, m) dm
\]

\[
= O_p \left( e^{-\eta_\alpha m} \right) + O_p \left( e^{-(1+p)\overline{\alpha}m} \right) = O_p \left( e^{-(\eta_\alpha \wedge (1+p)\overline{\alpha})} \right) = O_p \left( n^{-(\eta_\alpha \wedge (1+p)\overline{\alpha})} \right).
\]

For the discretization errors we use the following decomposition:

\[
\int_{m_{j-1}}^{m_j} \left[ e^{(i\alpha-1)m} \cdot O_t(\tau, m) - e^{(i\alpha-1)m_j} \cdot O_t(\tau, m_j) \right] dm
\]

\[
= \int_{m_{j-1}}^{m_j} \left[ \left( e^{(i\alpha-1)m} - e^{(i\alpha-1)m_j} \right) \cdot O_t(\tau, m_j) + e^{(i\alpha-1)m} \cdot O_t(\tau, m) - O_t(\tau, m_j) \right] dm.
\]

By applying the mean value theorem we have

\[
\left| e^{(i\alpha-1)m} - e^{(i\alpha-1)m_j} \right| \leq \left| iu - 1 \right| e^{(i\alpha-1)m} \cdot \Delta m_j \leq e^{m_j} \left( |u| \wedge 1 \right) \Delta m_j,
\]

and

\[
\left| e^{(i\alpha-1)m} \right| \left| O_t(\tau, m) - O_t(\tau, m_j) \right| \leq e^{m_j} \left| \frac{\partial O_t(\tau, m)}{\partial m} \right|_{m=m_j} \Delta m_j \leq e^{m_j} \left| \frac{\partial O_t(\tau, m)}{\partial K} \right|_{K=K} e^{m_j} F_t \Delta m_j
\]

\[
\leq \left| \frac{\partial O_t(\tau, m)}{\partial K} \right| \Delta m_j F_t \Delta m_j.
\]
where \( \tilde{m} = \log \frac{K}{F_t} \) is between \( m \) and \( m_j \).

Lemma \[\] implies that for all \( m \)
\[
\frac{O_t(\tau, m)}{F_t} \leq ce^{-[pm\vee-(1+q)m]},
\]
with some \( \mathcal{F}_t \)-adapted random variable \( c \). Furthermore, the derivative with respect to the strike price is the risk neutral distribution or survival functions, which can be bounded using the Markov inequality. In particular, for \( m > 0 \):
\[
\left| \frac{\partial O_t(\tau, m)}{\partial K} \right| = e^{-rt}Q(F_{t+}\tau > K) = e^{-rt}Q(f_{t+}\tau > e^m)
\leq e^{-rt}E[\mathcal{F}_t]e^{-(p+1)m},
\]
and for \( m < 0 \)
\[
\left| \frac{\partial O_t(\tau, m)}{\partial K} \right| = e^{-rt}Q(F_{t+}\tau < K) = e^{-rt}Q(f_{t+}\tau > e^{-m})
\leq e^{-rt}E[\mathcal{F}_t]e^{qm}.
\]

Therefore
\[
\left| \frac{\partial O_t(\tau, m)}{\partial K} \right| \leq de^{-[(p+1)m\vee-qm]}
\]
with some \( \mathcal{F}_t \)-adapted random variable \( d \). Combining all these inequalities together we get
\[
\left| \frac{1}{F_t} \int_{m_j-1}^{m_j} \left[ e^{(iu-1)m} \cdot O_t(\tau, m) - e^{(iu-1)m_j} \cdot O_t(\tau, m_j) \right] \, dm \right|
= \left| \frac{1}{F_t} \int_{m_j-1}^{m_j} \left[ e^{(iu-1)m} - e^{(iu-1)m_j} \right] \cdot O_t(\tau, m_j) + e^{(iu-1)m} \cdot (O_t(\tau, m) - O_t(\tau, m_j)) \right] \, dm \right|
\leq \left( c[u] \vee 1 \right) \Delta m_j e^{-m_j-1} e^{-[pm_j-1\vee-(1+q)m_j-1]} + de^{\Delta m}e^{-[(p+1)m_j-1\vee-qm_j-1]} \Delta m_j
\leq \tilde{c}e^{-[(p+1)m_j-1\vee-qm_j-1]}(\Delta m_j)^2.
\]

Then, for fixed \( \overline{m} \) and \( m_j \), and \( \Delta m \to 0 \), we have
\[
\zeta_3(u, \tau) = ut \sum_{j=2}^{n} \int_{m_{j-1}}^{m_j} \left[ e^{(iu-1)m} \cdot O_t(\tau, m) - e^{(iu-1)m_j} \cdot O_t(\tau, m_j) \right] \, dm = O_p(\Delta m). \tag{B.5}
\]

However, under the joint asymptotic scheme the order \[\] changes. In particular,
\[
\left| \sum_{j=2}^{n} \frac{1}{F_t} \int_{m_{j-1}}^{m_j} \left[ e^{(iu-1)m} \cdot O_t(\tau, m) - e^{(iu-1)m_j} \cdot O_t(\tau, m_j) \right] \, dm \right|
\leq \tilde{c} \sum_{j=2}^{n} e^{-[(p+1)m_j-1\vee-qm_j-1]}(\Delta m_j)^2
\leq \tilde{c} \Delta m \sum_{j=2}^{n} e^{-(p+1)m_j-1\vee-qm_j-1} \Delta m_j.
\]
The sum on the right hand side of the inequality is the Riemann approximation that converges to the following integrals:
\[
\sum_{j=2}^{n} e^{-(p+1)m_{j-1} - qm_{j-1}} \Delta m_j \rightarrow \int_{\bar{m}}^{m} e^{-(p+1)\bar{m} - qm} \, dm = \int_{m}^{0} e^{qm} \, dm + \int_{0}^{\bar{m}} e^{-(p+1)m} \, dm
\]
\[
= \mathcal{O}_p \left( n^{-q} \right) + \mathcal{O}_p \left( n^{-(p+1)\bar{m}} \right)
\]
\[
= \mathcal{O}_p \left( n^{-(q^{\wedge} \wedge (p+1)\bar{m}))} \right).
\]

Given Assumption [3(ii)] on the log-moneyness grid, we can bound \( \Delta m \) as
\[
\frac{\bar{m} - m}{\eta n} \geq \Delta m \geq \frac{\bar{m} - m}{n}.
\]

Hence \( \Delta m = \mathcal{O}_p \left( \frac{\log n}{n} \right) \). Then the order of the discretization error under the joint asymptotic scheme is
\[
\zeta_t^{(3)}(u, \tau) = \mathcal{O}_p \left( n^{-(q^{\wedge} \wedge (p+1)\bar{m}))} \right) \mathcal{O}_p \left( \frac{\log n}{n} \right) = \mathcal{O}_p \left( \frac{\log n}{n^{1+q^{\wedge} \wedge (p+1)\bar{m})}} \right).
\]

**Proof of Proposition 1:**

Using Lemma 2, Assumption 3 on the moments of the underlying process and observation error Assumption 2, we can decompose the CCF approximation as
\[
\hat{\phi}_t(u, \tau) - \phi_t(u, \tau) = \zeta_t^{(1)}(u, \tau) + \mathcal{O}_p \left( \frac{\log n}{n^{1+q^{\wedge} \wedge (p+1)\bar{m})}} \right)
\]
\[
= \zeta_t^{(1)}(u, \tau) + \mathcal{O}_p \left( n^{-2(2 \wedge \bar{m})} \right)
\]
with
\[
\zeta_t^{(1)}(u, \tau) = -u \sum_{j=2}^{n} e^{(i(u-1)m_{j})} \cdot \zeta_t(\tau, m_j) \Delta m_j.
\]

We now show that \( \zeta_t^{(1)}(u, \tau) = \mathcal{O}_p \left( \sqrt{\frac{\log n}{n}} \right) \). In fact, the standard deviation of the observation errors is proportional to the Black-Scholes vega, which decreases with \( |m| \rightarrow \infty \). More specifically, the vega is given by
\[
\nu_t(\tau, m) = F_t \sqrt{\tau} N'(d_+)
\]
\[
d_+ = -mv^{-1/2} + \frac{1}{2}v^{1/2},
\]
where \( N'(x) \) is the standard normal pdf and \( v(m) := \kappa^2(\tau, m)\tau \). Hence
\[
\nu_t^2(\tau, m) = F_t^2 \frac{1}{2\pi} e^{-d_+^2} = F_t^2 \frac{1}{2\pi} e^{-(v^{-1}m^2 - m + 1)v}.
\]
Therefore, given Assumption 2, we get

\[
\mathbb{E} \left[ \zeta_t^{(1)}(u, \tau) \right] \leq |u_t|^2 \sum_{j=2}^{n} e^{-2m_j} \cdot \mathbb{E} \left[ \zeta_t(\tau, m_j) \right] (\Delta m_j)^2
\]

\[
\leq |u_t|^2 \sum_{j=2}^{n} e^{-2m_j} \left( \tau \frac{1}{2 \pi} e^{-\frac{1}{4}v_j(\Delta m_j)^2 - m_j + \frac{1}{4}v_j} \right) (\Delta m_j)^2
\]

\[
\leq \tilde{C}_t \Delta m \sum_{j=2}^{n} v_j e^{-v_j - m_j - \frac{1}{4}v_j} \Delta m_j
\]

where \( d_-(m) := -mv^{-1/2} - \frac{1}{2}v^{1/2}(m) \) and \( \tilde{C}_t \) is some \( \mathcal{F}_t \)-adapted random variable, that does not depend on the log-moneyness level. Then the right-hand side summation converges to

\[
\int_{-\infty}^{\infty} v(m) \exp \left( -d_-(m) \right) dm =: \int_{-\infty}^{\infty} h(m) dm,
\]

provided that the function \( h(m) \) is integrable. To show the latter, we focus on the tail behavior since \( h \) is continuous and bounded on the definite interval \((m, \overline{m})\). For that, we will make use of the asymptotic results of \( \text{Lee (2004)} \):

\[
\limsup_{m \to -\infty} \frac{v(m)}{|m|} = \beta_t^* \text{ with } \beta_t^* \in [0, 2] \text{ and } \frac{1}{2\beta_t^*} + \frac{\beta_t^*}{8} - \frac{1}{2} = \sup \{ q : \mathbb{E}[F_t^{-q}|\mathcal{F}_t] < \infty \},
\]

\[
\limsup_{m \to \infty} \frac{v(m)}{|m|} = \beta_r^* \text{ with } \beta_r^* \in [0, 2] \text{ and } \frac{1}{2\beta_r^*} + \frac{\beta_r^*}{8} - \frac{1}{2} = \sup \{ p : \mathbb{E}[F_t^{1+p}|\mathcal{F}_t] < \infty \}.
\]

That is, for \( m < 0 \), the implied variance \( v(m) \) grows at most as fast as \(-\beta_t^* m\) with some \( \beta_t^* \). Given Assumption 3 on moments of the reciprocal process, we have \( \beta_t^* < 1 \), which implies that

\[
h(m) = v \exp \left( -v^{-1}m^2 - m - \frac{1}{4}v \right) \leq -\beta_t^* m \exp \left( \frac{m}{\beta_t^*} - m \right)
\]

is integrable on the left tail. The integrability on the right tail is achieved even without the use of moment conditions. Therefore, since the summation converges under the joint asymptotic scheme to the integral above, we have that \( \zeta_t^{(1)}(u, \tau) = O_p \left( \sqrt{\Delta m} \right) = O_p \left( \sqrt{\log n} \right) \).

From Assumption 2 it also follows that \( \mathbb{E}[\zeta_t^{(1)}(u, \tau)|\mathcal{F}_t] = 0 \), while the discretization and truncation errors \( \zeta_t^{(2)}(u, \tau) \) and \( \zeta_t^{(3)}(u, \tau) \) are \( \mathcal{F}_t \)-measurable. Therefore, the covariance and the pseudo-covariance terms of the CCF approximation are given by the second moments of the
observation errors $\zeta_{t}^{(i)}(u, \tau)$, that is,

$$\text{Cov}(\zeta_{t}^{(i)}(u, \tau), \zeta_{t}^{(i)}(u, \tau)) := E \left[ (\zeta_{t}^{(i)}(u, \tau) - E[\zeta_{t}^{(i)}(u, \tau)]) \left( \zeta_{t}^{(i)}(u, \tau) - E[\zeta_{t}^{(i)}(u, \tau)] \right) \right] \mathcal{F}_{t}$$

$$= E \left[ \zeta_{t}^{(1)}(u, \tau) \zeta_{t}^{(1)}(-u, \tau) \right] \mathcal{F}_{t}$$

$$= u_{i,t} u_{j,t} \sum_{j=2}^{n} e^{i(u_{i} - u_{j}) - 2m_{j}} \cdot \sigma_{T}^{2} \tau \cdot m \cdot (\Delta m_{j})^{2}$$

$$= \sigma_{\kappa}^{2} \cdot u_{i,t} u_{j,t} \sum_{j=2}^{n} e^{i(u_{i} - u_{j}) - 2m_{j}} \cdot \kappa_{T}^{2} \tau \cdot m \cdot \nu_{T}^{2} \tau \cdot m \cdot (\Delta m_{j})^{2}$$

$$= \sigma_{\kappa}^{2} \cdot \gamma_{t}(u_{i}, u_{j}),$$

and

$$\text{PCov}(\zeta_{t}^{(i)}(u, \tau), \zeta_{t}^{(i)}(u, \tau)) := E \left[ (\zeta_{t}^{(i)}(u, \tau) - E[\zeta_{t}^{(i)}(u, \tau)]) \left( \zeta_{t}^{(i)}(u, \tau) - E[\zeta_{t}^{(i)}(u, \tau)] \right) \right] \mathcal{F}_{t}$$

$$= E \left[ \zeta_{t}^{(1)}(u, \tau) \zeta_{t}^{(1)}(u, \tau) \right] \mathcal{F}_{t}$$

$$= \sigma_{\kappa}^{2} \cdot u_{i,t} u_{j,t} \sum_{j=2}^{n} e^{i(u_{i} + u_{j}) - 2m_{j}} \cdot \kappa_{T}^{2} \tau \cdot m \cdot \nu_{T}^{2} \tau \cdot m \cdot (\Delta m_{j})^{2}$$

$$= \sigma_{\kappa}^{2} \cdot c_{t}(u_{i}, u_{j}),$$

for any $u_{i}, u_{j} \in \mathcal{U}$, where $\bar{z}$ denotes the complex conjugate of a complex number $z \in \mathbb{C}$. In other words, the covariances of the total measurement errors in the CCF approximation are determined by the properties of the observation errors in option prices only. Note that the terms $\gamma_{t}(u_{i}, u_{j}, \tau)$ and $c_{t}(u_{i}, u_{j}, \tau)$ depend only on option’s characteristics such as BSIV, BS vega and moneyness levels. That is, the covariance terms are parametrized using only a single parameter $\sigma_{\kappa}$ that reflects the variance of the observation errors in option prices.

The measurement equation for the filtering problem is given in terms of the log CCF. Therefore, by applying a Taylor-series expansion to the difference of the logs and using the error decomposition of the CCF approximation we have

$$\xi_{t}(u, \tau) := \log \hat{\phi}_{t}(u, \tau) - \log \phi_{t}(u, \tau) = \log \left( 1 + \frac{\zeta_{t}^{(1)}(u, \tau) + \zeta_{t}^{(2)}(u, \tau) + \zeta_{t}^{(3)}(u, \tau)}{\phi_{t}(u, \tau)} \right)$$

$$= \xi_{t}^{(1)}(u, \tau) + r_{t}(u, \tau),$$

where

$$\xi_{t}^{(1)}(u, \tau) := \frac{\zeta_{t}^{(1)}(u, \tau)}{\phi_{t}(u, \tau)} = O_{p}\left( \sqrt{\frac{\log n}{n}} \right) \text{ and } r_{t}(u, \tau) = O_{p}\left( n^{-2(2/3)} \right).$$

We note that the remainder term collects the log-linearization of the truncation and discretization errors and higher-order terms from a Taylor-series expansion.
After stacking each component of the measurement equation (12), as well as the observation errors $\xi_t^{(1)}(u, \tau)$ and remainder $r_t(u, \tau)$ along arguments, real and imaginary parts, and maturity, we get state space measurement equation (19) in Proposition 1.

To derive the covariance matrix of the measurement errors, we first consider the covariance and pseudo-covariance matrices of the stacked vector $\xi_t^{(1)} = \left(\xi_t^{(1)}(u_1, \tau), \xi_t^{(1)}(u_2, \tau), \ldots, \xi_t^{(1)}(u_q, \tau)\right)^T$ for a fixed time $t$ and time-to-maturity $\tau$ are given by

$$\Gamma_{t,\tau} := \mathbb{E} \left[\xi_{t,\tau}^{(1)} \xi_{t,\tau}^{(1)\top}\right] = \begin{bmatrix} \mathbb{E}[\xi_t^{(1)}(u_i, \tau)\xi_t^{(1)}(-u_j, \tau)] \end{bmatrix}_{1 \leq i, j \leq q} \tag{B.9}$$

$$C_{t,\tau} := \mathbb{E} \left[\xi_{t,\tau}^{(1)} \xi_{t,\tau}^{(1)\top}\right] = \begin{bmatrix} \mathbb{E}[\xi_t^{(1)}(u_i, \tau)\xi_t^{(1)}(u_j, \tau)] \end{bmatrix}_{1 \leq i, j \leq q} \tag{B.10}$$

Since the $\xi_t^{(1)}$ is the complex-valued random vector, the covariance matrix of the stacked real and imaginary parts of $\xi_t^{(1)}$ is of the following form:

$$H_{t,\tau} = \text{Var} \left[\begin{bmatrix} \Re(\xi_{t,\tau}^{(1)}) \\ \Im(\xi_{t,\tau}^{(1)}) \end{bmatrix}\right] = \begin{bmatrix} \frac{1}{2}\Re(\Gamma_{t,\tau} + C_{t,\tau}) & \frac{1}{2}\Im(-\Gamma_{t,\tau} + C_{t,\tau}) \\ \frac{1}{2}\Im(\Gamma_{t,\tau} + C_{t,\tau}) & \frac{1}{2}\Re(-\Gamma_{t,\tau} + C_{t,\tau}) \end{bmatrix}$$

$$\mathbb{E}[\xi_{t,\tau}] = 0 \text{ for } s \neq t, \text{ and their covariance matrix has a block-diagonal form: } H_t = \text{blkdiag}\{H_{t,1}, \ldots, H_{t,k}\}.$$}

Given Assumption 2, the error terms $\zeta_t^{(1)}$ and $\xi_t^{(1)}$ are conditionally independent along maturity and time. This implies that the stacked along maturities measurement errors $\varepsilon_t$ are also conditionally independent, thus $\mathbb{E}[][\varepsilon_t] = 0$ for $s \neq t$, and their covariance matrix has a block-diagonal form: $H_t = \text{blkdiag}\{H_{t,1}, \ldots, H_{t,k}\}$.

The disturbance term in the state updating equation is given by $\eta_{t+1} = x_{t+1} - \mathbb{E}[x_{t+1} | \mathcal{F}_t]$. Therefore, $\eta_t$ is martingale difference sequences, thus $\mathbb{E}[\eta_{t}] = 0$ for $s \neq t = 1, \ldots, T$.

Since the measurement errors $\varepsilon_t$ have zero mean conditional on filtration $\mathcal{F}_t$, we also have that $\mathbb{E}[\varepsilon_t x_t] = 0$. Given the state process is stationary and the initial condition is the unconditional mean, $\mathbb{E}[][x_t] = 0$ and $\mathbb{E}[\eta_{t+1} x_i^T] = 0$. All of these imply that $\mathbb{E}[\varepsilon_t x_t] = 0$ for all $s, t = 1, \ldots, T$.

**Appendix C Conditional Moments**

In this appendix, we show how the conditional mean and variance can be computed for the AJD class of models. In particular, we derive the closed-form expressions for the conditional mean and variance in the univariate case and discuss how these moments can be obtained in the multivariate setting numerically with little computational costs. While semi-closed expressions are also available in the multivariate setting, they are more cumbersome to work with in practice since they require matrix exponential and integrations.
We start with considering the univariate version of the AJD process in (4), denoted as $x_t$:

$$dx_t = \mu(x_t)dt + \sigma(x_t)dW_t + Z_t dN_t,$$

with $\mu(x_t) = k_0 + k_1 x_t$, $\sigma^2(x_t) = h_0 + h_1 x_t$, $\lambda(x_t) = l_0 + l_1 x_t$, where all coefficients are real-valued numbers and the standard Brownian motion $W_t$ and the counting process $N_t$ are univariate processes. The jump size distribution is independent of time and of any form of randomness in the model. We further assume Assumption 1 to hold. For more notational details see Section 2.2 and Duffie et al. (2000). Furthermore, for notational simplicity, let us introduce the following terms:

$$g_0 := k_0 + l_0 J_1, \quad g_1 := k_1 + l_1 J_1, \quad J_1 := \mathbb{E}[Z], \quad J_2 := \mathbb{E}[Z^2].$$

An infinitesimal generator $D$ defined at a bounded $C^2$ function $f: D \to \mathbb{R}$ is

$$D f(x) = f_x(x)\mu(x) + \frac{1}{2} f_{xx}(x)\sigma(x)^2 + \lambda(x) \int_{\mathbb{R}} \left[ f(x + z) - f(x) \right] d\nu(z),$$

where $f_x$ and $f_{xx}$ are the bounded first and second derivatives, respectively. The Dynkin’s formula yields

$$\mathbb{E}[f(x_T)|\mathcal{F}_t] = f(x_t) + \mathbb{E} \left[ \int_t^T D f(x_s) ds \bigg| \mathcal{F}_t \right].$$

Therefore, we can find the conditional moments by applying Dynkin’s formula for $f(x) = x$:

$$\mathbb{E}[x_T|\mathcal{F}_t] = x_t + \mathbb{E} \left[ \int_t^T \left( \mu(x_s) + \lambda(x_s) \int_{\mathbb{R}} z d\nu(z) \right) ds \bigg| \mathcal{F}_t \right]$$

$$= x_t + \mathbb{E} \left[ \int_t^T (k_0 + k_1 x_s + (l_0 + l_1 x_s) J_1) ds \bigg| \mathcal{F}_t \right]$$

$$= x_t + \int_t^T (k_0 + l_0 J_1 + (k_1 + l_1 J_1) \mathbb{E}[x_s|\mathcal{F}_t]) ds$$

$$= x_t + \int_t^T (g_0 + g_1 \mathbb{E}[x_s|\mathcal{F}_t]) ds,$$

where Fubini’s theorem is used in the third line. Hence, we can obtain the first conditional moment by solving the ODE:

$$d\mathbb{E}[x_s|\mathcal{F}_t] = (g_0 + g_1 \mathbb{E}[x_s|\mathcal{F}_t]) ds,$$

with the initial condition $\mathbb{E}[x_t|\mathcal{F}_t] = x_t$. Therefore, the conditional expectation is given by

$$m_s(T) := \mathbb{E}[x_T|\mathcal{F}_t] = e^{g_T(T-t)} x_t + \frac{g_0}{g_1} \left( e^{g_T(T-t)} - 1 \right). \quad (C.2)$$

Now we are interested in deriving the conditional variance:

$$\text{Var}(x_T|\mathcal{F}_t) = \mathbb{E}[(x_T - \mathbb{E}[x_T|\mathcal{F}_t])^2|\mathcal{F}_t].$$

Note that

$$x_T - \mathbb{E}[x_T|\mathcal{F}_t] = \mathbb{E}[x_T|\mathcal{F}_t] - \mathbb{E}[x_T|\mathcal{F}_t] = \int_t^T d\mathbb{E}[x_T|\mathcal{F}_s] = \int_t^T dm_s(T).$$
The dynamics of the conditional mean for fixed $T > t$ can be obtained by using Ito’s lemma:
\[
dm_t(T) = \left[-g_1e^{g_1(T-t)}x_t - g_0e^{g_1(T-t)}\right] dt + e^{g_1(T-t)}(\mu(x_t)dt + \sigma(x_t)dW_t) + e^{g_1(T-t)}Z_t dN_t
\]
\[
e^{g_1(T-t)} \left[-(l_0 + l_1x_t)J_1 dt + \sigma(x_t)dW_t + Z_t dN_t\right].
\]

Note that the process $m_t(T)$ for fixed $T$ is a local martingale. Thus, we can use the Ito isometry to get the conditional variance:
\[
\text{Var}(x_T|\mathcal{F}_t) = \mathbb{E}_t \left[ \left( \int_t^T dm_s(T) \right)^2 \right] = \mathbb{E}_t \left[ \int_t^T e^{2g_1(T-s)} \sigma^2(x_s) ds \right] + J_2 \cdot \mathbb{E}_t \left[ \int_t^T e^{2g_1(T-s)} \lambda(x_s) ds \right]
\]
\[
= \int_t^T e^{2g_1(T-s)} (h_0 + h_1 \mathbb{E}_t[x_s]) ds + J_2 \cdot \int_t^T e^{2g_1(T-s)} (l_0 + l_1 \mathbb{E}_t[x_s]) ds
\]
\[
= (h_0 + l_0J_2) \int_t^T e^{2g_1(T-s)} ds + (h_1 + l_1J_2) \cdot \int_t^T e^{2g_1(T-s)} \mathbb{E}_t[x_s] ds,
\]
where we have used Fubini’s theorem to interchange the expectation and integration. Given the conditional expectation, the second integral can be further simplified:
\[
\int_t^T e^{2g_1(T-s)} \mathbb{E}_t[x_s] ds = \int_t^T e^{2g_1(T-s)} \left[ e^{g_1(s-t)}x_t + \frac{g_0}{g_1} \left( e^{g_1(s-t)} - 1 \right) \right] ds
\]
\[
= e^{2g_1T} \left[ \int_t^T e^{-g_1(s+t)} x_t + \frac{g_0}{g_1} \left( e^{-g_1(s+t)} - e^{-2g_1t} \right) ds \right]
\]
\[
= e^{2g_1T} \left[ -\frac{1}{g_1} \left( e^{-g_1(T-t)} - e^{-2g_1t} \right) x_t + \frac{g_0}{g_1} \left( e^{-g_1(T-t)} - e^{-2g_1t} \right) + \frac{g_0}{2g_1} \left( e^{-2g_1T} - e^{-2g_1t} \right) \right]
\]
\[
= -\frac{1}{g_1} \left( e^{g_1(T-t)} - e^{2g_1(T-t)} \right) x_t + \frac{g_0}{2g_1} \left( -2e^{g_1(T-t)} + 2e^{2g_1(T-t)} + 1 - e^{2g_1(T-t)} \right)
\]
\[
= -\frac{1}{g_1} \left( e^{g_1(T-t)} - e^{2g_1(T-t)} \right) x_t + \frac{g_0}{2g_1} \left( 1 - e^{g_1(T-t)} \right)^2.
\]
Therefore, the conditional variance in the univariate case is given by
\[
\text{Var}(x_T|\mathcal{F}_t) = -\frac{1}{2g_1} \left( h_0 + l_0J_2 \right) \left( 1 - e^{2g_1(T-t)} \right)
\]
\[
-\frac{1}{2g_1} \left( h_1 + l_1J_2 \right) \left[ 2g_1 \left( e^{g_1(T-t)} - e^{2g_1(T-t)} \right) x_t - g_0 \left( 1 - e^{g_1(T-t)} \right)^2 \right]. \tag{C.3}
\]

Equations \(C.2\) and \(C.3\) are the basis for the formulation of the transition equation \(20\) as discussed in Section \(3.1\). It is crucial for our application to note that the conditional mean \(C.2\) and conditional variance \(C.3\) of the univariate AJD process $x_T$ at time $T > t$ conditional on information at time $t$ are affine functions in $x_t$. The affinity of the conditional moments yields the linear state updating equation, which, in turn, allows us to use the linear Kalman filtering technique.

Using the same reasoning, it is also possible to derive the analogues of equations \(C.2\) and \(C.3\) for the multivariate AJD process. However, these expressions involve matrix exponential and their integrations, which makes it cumbersome to work with analytically. Fortunately, the conditional moments can be easily obtained by differentiating the CCF, which is known in a
semi-closed form for the AJD class (see Section 2.2). The finite difference approximations of the first and second derivatives around the origin yield very precise results with little additional computational costs. One can also easily verify that the affine property of the conditional moments holds in the multivariate case by differentiating the exponentially-affine CCF.

Appendix D  Option Extrapolation Scheme

In this appendix, we discuss in details the extrapolation scheme we adopt to extrapolate option prices beyond the observable range of strikes. As discussed in Section 5, we extrapolate total implied variance linearly in log-moneyness since it is consistent with the Roger Lee’s moment formula.

In fact, the asymptotic result of Lee (2004) for extreme strikes states that the implied volatility wings should not grow faster than $|m|^{1/2}$ and should not grow slower than $|m|^{1/2}$, unless the underlying asset has finite moments of all orders. In particular, Lee (2004) shows that

$$\limsup_{m \to -\infty} \frac{\kappa^2(m, \tau) \cdot \tau}{|m|} = \beta_l^*$$

with $\beta_l^* \in [0, 2]$ and (D.1)

$$\limsup_{m \to \infty} \frac{\kappa^2(m, \tau) \cdot \tau}{|m|} = \beta_r^*$$

with $\beta_r^* \in [0, 2]$. (D.2)

Furthermore, he establishes that there is a one-to-one correspondence between $\beta_r^*$ and the number of moments of the underlying $S_\tau$, and $\beta_l^*$ and the number of moments of $1/S_\tau$. For instance, for the right tail the moment formula for implied volatility is

$$\frac{1}{2\beta_r^*} + \frac{\beta_r^*}{8} - \frac{1}{2} = \sup\{p : \mathbb{E}[S_\tau^{1+p}] < \infty\}.$$  

This result allows us to conjecture the asymptotically valid parametrization to extrapolate the implied volatility beyond the observable range of strikes. In other words, we assume that the total variance $v(m, \tau) = \kappa^2(m, \tau) \cdot \tau$ is linear in log-moneyness:

$$v(m, \tau) = \alpha + \beta \cdot m.$$

The intercept coefficients are introduced to guarantee continuity between interpolation and extrapolation domains. These coefficients are exactly determined by the smallest and largest observable strike prices (or corresponding log-moneyness levels, denoted by $m_l$ and $m_r$, respectively) given the slopes $\beta_l$ and $\beta_r$ for the left and right tails, respectively:

$$\alpha_l = v(m_l, \tau) - \beta_l \cdot m_l \quad \text{and} \quad \alpha_r = v(m_r, \tau) - \beta_r \cdot m_r.$$

Therefore, what we have left to do is to establish the choice of the coefficients $\beta_l$ and $\beta_r$. Note that the moment formulas are devoted for the upper bounds (D.1) and (D.2). Furthermore, finding the number of finite moments of the underlying would require parametrizing the dynamics of $S_\tau$.  

15Note that the flat-extrapolation assumes the log-normality of the underlying asset in the tails. Since all moments of the log-normal distribution exist, it means that the slope has to be indeed zero.
parametric model afterwards. Instead, we simply use the derivative of the fitted cubic spline at the last observable strikes to determine the slopes:

\[
\beta_l = -\left. \frac{\partial v(m, \tau)}{\partial m} \right|_{m=m_l} \quad \text{and} \quad \beta_r = \left. \frac{\partial v(m, \tau)}{\partial m} \right|_{m=m_r}.
\]

Note that Lee’s bounds for the slopes are asymptotic result. Therefore, the slopes \( \beta_l \) and \( \beta_r \) should also satisfy these bounds, which translates in \( \beta_l \in [-2, 0] \) for the left slope. However, arbitrage-free conditions for our parametrization might possibly be tighter since we are in a finite setting. To obtain these conditions, we closely follow the derivation sketched in [Jackel (2014)].

First, similar to [Gatheral and Jacquier (2014)] we introduce a function \( w : \mathbb{R} \to \mathbb{R} \):

\[
w(m) := \left(1 - \frac{m}{2} \cdot \frac{v'(m)}{v(m)} \right)^2 - \frac{v'(m)}{4} \left(\frac{1}{4} + \frac{1}{v(m)}\right) + \frac{1}{2} v''(m).
\]

Then the second derivative of an option with respect to the strike price can be expressed via this function as

\[
\frac{\partial^2 C(K, \tau)}{\partial K^2} = e^{-r\tau} \frac{\varphi(d_2)}{\sqrt{v(m)} R} w(m),
\]

where \( \varphi(x) \) is the pdf of the standard normal distribution and \( d_2 = -\frac{m}{\sqrt{v(m)}} - \frac{\sqrt{\alpha}}{2} \). Since the second derivative of an option yields the risk-neutral density, to guarantee the arbitrage-freeness of the slice any extrapolation (and interpolation) methods should satisfy \( w(m) \geq 0 \) for all \( m \in \mathbb{R} \). See also [Gatheral and Jacquier (2014)] for more details. In the following, we investigate this inequality for our chosen parametrization.

Substituting \( v(m) = \alpha + \beta \cdot m \) into the inequality \( w(m) \geq 0 \) we have

\[
w(m) = \left(1 - \frac{m}{2} \cdot \frac{\beta}{v(m)} \right)^2 - \frac{\beta^2}{4} \left(\frac{1}{4} + \frac{1}{v(m)}\right) \geq 0.
\]

Multiplying this inequality by non-negative factor \( 4 \cdot v(m)^2 \) results in

\[
(2v(m) - m\beta)^2 - \beta^2 \left(\frac{1}{4} v(m)^2 + v(m)\right) \geq 0
\]

\[
(2\alpha + \beta m)^2 - \beta^2 \left(\alpha^2 + 4\alpha + (2\alpha\beta + 4\beta)m + \beta^2 m^2\right) \geq 0
\]

\[
\beta^2 \left(1 - \frac{\beta^2}{4}\right) m^2 + \left(4\alpha - \frac{\beta^2}{4}(2\alpha + 4)\right) \beta m + 4\alpha^2 - \frac{\beta^2}{4}(\alpha^2 + 4\alpha) \geq 0
\]

\[
\frac{1}{4} \beta^2 (4 - \beta^2) m^2 + (4\alpha - \frac{1}{2} \beta^2 \alpha - \beta^2) \beta m + 4\alpha^2 - \frac{1}{4} \beta^2 \alpha^2 - \alpha \beta^2 \geq 0 \quad \text{(D.3)}
\]

The left-hand side is the quadratic function in \( m \) with non-negative quadratic coefficient \( \frac{1}{4} \beta^2 (4 - \beta^2) \) since \( |\beta| \leq 2 \). The discriminant of this quadratic polynomial is \( \Delta = \beta^4 (\alpha^2 - 4\alpha + \beta^2) \). Thus, if \( \Delta < 0 \), no real roots exist, and hence, \( w(m) \geq 0 \) for all \( \beta \) and \( m \). Therefore, for the right tail we have

\[
\Delta < 0 \iff \alpha^2 - 4\alpha + \beta^2 < 0
\]

\[
(v_r - \beta m_r)^2 - 4(v_r - \beta m_r) + \beta^2 < 0
\]

\[
(m_r^2 + 1)\beta^2 - 2m_r(v_r - 2)\beta + v_r^2 - 4v_r < 0
\]
where we have substituted values for $\alpha$, determined by the largest extreme strike price with the moneyness $m_r$ and the total variance $v_r := v(m_r)$. The discriminant of the quadratic equation on the left-hand side is given by $\Delta_r = 4(4m_r^2 - v_r^2 + 4v_r)$. Assuming $v_r < 4$ we get that the real roots of this polynomial have different signs. Therefore, we get a condition:

\[
0 < \beta_r < \frac{m_r(v_r - 2) + \sqrt{\Delta_r}}{m_r^2 + 1} \quad \text{if } \Delta_r := 4m_r^2 - v_r^2 + 4v_r > 0. \tag{D.4}
\]

If $\Delta_r \leq 0$, then $\Delta > 0$. Assuming the positive density at the largest strike, that is, $w(m_r) > 0$, we only need to ensure that the global minimum of the quadratic function on the left-hand side of (D.3) is to the left of $m_r$:

\[
\frac{\beta^2\alpha + 2\beta^2 - 8\alpha}{\beta(4 - \beta^2)} < m_r
\]

\[
(v_r - \beta m_r + 2)\beta^2 - 8(v_r - \beta m_r) < m_r\beta(4 - \beta^2)
\]

\[
(v_r + 2)\beta^2 + 4m_r\beta - 8v_r < 0.
\]

Since the discriminant of this quadratic function is $\Delta_1 = 16(m_r^2 + 2v_r^2 + 4v_r) > 0$ we get another condition on $\beta_r$:

\[
0 < \beta_r < \frac{-2m_r + 2\sqrt{m_r^2 + 2v_r^2 + 4v_r}}{v_r + 2}. \tag{D.5}
\]

Combining (D.4) and (D.5) we get the arbitrage-free condition for the right tail slope $\beta_r$:

\[
0 \leq \beta_r < \min(\beta_{\text{max}}, 2)
\]

with

\[
\beta_{\text{max}} = \begin{cases} 
\max \left( \frac{m_r(v_r - 2) + \sqrt{\Delta_r}}{m_r^2 + 1}, \frac{-2m_r + 2\sqrt{m_r^2 + 2v_r^2 + 4v_r}}{v_r + 2} \right) & \text{if } \Delta_r > 0 \\
-2m_r + 2\sqrt{m_r^2 + 2v_r^2 + 4v_r} & \text{if } \Delta_r \leq 0.
\end{cases}
\]

Note that since the right boundary in (D.5) is always positive, $\beta_{\text{max}} > 0$ regardless of whether $v_r < 4$ or not. Thus, the assumption imposed above on $v_t < 4$ is redundant.

The left-tail slope boundaries can be obtained in a similar way by substituting the observable option price $v_l := v(m_l)$ with the smallest strike price $m_l$ and taking the negative roots of quadratic polynomials where necessary:

\[
\max(\beta_{\text{min}}, -2) < \beta_l \leq 0
\]

with

\[
\beta_{\text{min}} = \begin{cases} 
\max \left( \frac{m_l(v_l - 2) - \sqrt{|\Delta_l|}}{m_l^2 + 1}, \frac{-2m_l - 2\sqrt{m_l^2 + 2v_l^2 + 4v_l}}{v_l + 2} \right) & \text{if } \Delta_l > 0 \\
-2m_l + 2\sqrt{m_l^2 + 2v_l^2 + 4v_l} & \text{if } \Delta_l \leq 0.
\end{cases}
\]

where $\Delta_l := 4m_l^2 - v_l^2 + 4v_l$. 

50
Appendix E  Additional Simulation and Empirical Results

In this appendix we provide the Monte Carlo results for another two option pricing specifications. In particular, we consider the specification with the Gaussian jump size distribution and two separate jump processes for positive and negative jumps.

E.1  Additional simulation results

E.1.1  SVCJ

We additionally illustrate the developed estimation approach based on the widely used ‘double-jump’ stochastic volatility model of Duffie et al. (2000) with Gaussian jump size distribution. In particular, we assume the following process for the log forward price under the both $\mathbb{P}$ and $\mathbb{Q}$ probability measures:

$$\begin{align*}
\frac{d \log F_t}{dt} &= \left( -\frac{1}{2} v_t - \mu \lambda_t \right) dt + \sqrt{v_t} dW_{1,t} + Z_t dN_t, \\
\frac{d v_t}{dt} &= \kappa (\bar{v} - v_t) dt + \sigma \sqrt{v_t} dW_{2,t} + Z_v^t dN_t,
\end{align*}$$

(E.1)

(E.2)

where two Brownian motions $W_1$ and $W_2$ are assumed to be correlated with the coefficient $\varrho$; $N_t$ is the Poisson jump process with intensity $\lambda_t$; $Z_v^t \sim \text{exp}(1/\mu_v)$ are the jumps in volatility and $Z_t \sim \mathcal{N}(\mu_j, \sigma^2_j)$ are the jumps in prices. Given the jump size distributions, the expected relative jump size in returns $\mu = \exp(\mu_j + \frac{1}{2} \sigma^2_j) - 1$. We further extend the specification by letting the intensity to be multiple the stochastic variance as in Pan (2002), that is, $\lambda_t = \delta v_t$.

The main difference from the SVCDEJ specification in Section 4.1 is Gaussian jump sizes in returns and the jump size in volatility being independent from jump sizes in returns.

The discounted marginal CCF of the log forward prices in the SVCJ model is given by

$$\phi_t(u, \tau) = e^{-rt} \mathbb{E}^{\mathbb{Q}}[e^{iu \cdot X_t + \tau} | \mathcal{F}_t] = e^{\alpha(u, \tau) + \beta_1(u, \tau) v_t + \xi_t(u, \tau)},$$

(E.3)

where $u \in \mathbb{R}$ is an argument and $\alpha(u, \tau)$ and $\beta(u, \tau)$ are solutions to the complex-valued ODE system in time:

$$\begin{align*}
\dot{\beta}_1(s) &= 0, \\
\dot{\beta}_2(s) &= -\left( \mu \delta + \frac{1}{2} (1 - \beta_1(s)) \right) \beta_1(s) - \kappa \beta_2(s) + \rho \sigma v \beta_1(s) \beta_2(s) + \frac{1}{2} \sigma^2 v \beta_2^2(s) \\
\dot{\alpha}(s) &= \kappa \bar{v} \beta_2(s) - r,
\end{align*}$$

with initial conditions $\beta_1(0) = iu$, $\beta_2(0) = 0$ and $\alpha(0) = 0$. Here the ‘jump transform’ $\chi(\beta_1, \beta_2) = \exp(\beta_1 \mu_j + \frac{1}{2} \beta_1^2 \sigma^2_j) (1 - \beta_2 \mu_v)^{-1}$. Therefore, as in the SVCDEJ specification, the linear relation between the log of the option-spanned CCF and the state vector is given by

$$\log \hat{\phi}_t(u, \tau) = \alpha(u, \tau) + \beta_2(u, \tau) v_t + \xi_t(u, \tau), \quad u \in \mathbb{R},$$

where $\tau > 0$ is the time-to-maturity of available options and $\xi_t(u, \tau)$ is the measurement error term. We use this linear relation to construct the measurement equation as discussed in Section 3.1.
The conditional mean and variance of the latent stochastic volatility process are given by

\[ E[v_{t+1}|F_t] = e^{g_1 \Delta t} v_t + \frac{g_0}{g_1} (e^{g_1 \Delta t} - 1), \quad (E.4) \]

\[ \text{Var}(v_{t+1}|F_t) = -\delta^2 \mu^2 \left[ 2g_1 (e^{g_1 \Delta t} - e^{2g_1 \Delta t}) v_t - g_0 (1 - e^{g_1 \Delta t})^2 \right], \quad (E.5) \]

with \( g_0 = \kappa \bar{v} \) and \( g_1 = -\kappa + \delta \mu_v \). Equations \( (E.4) \) and \( (E.5) \) are used to define the state updating equation:

\[ v_{t+1} = c + T v_t + \eta_{t+1} \quad (E.6) \]

where \( c = \frac{g_0}{g_1} (e^{g_1 \Delta t} - 1) \), \( T = e^{g_1 \Delta t} \) and \( \text{Var}(\eta_{t+1}|F_t) = \text{Var}(v_{t+1}|F_t) \). We also impose the Feller condition \( 2\kappa \bar{v} > \sigma^2 \) and the covariance stationary condition \( \kappa > \delta \mu_v \).

Note: This table provides Monte Carlo simulation results for the SVCJ model. We use \( T = 500 \) time points with \( \Delta t = 1/250 \). The initial values are set to \( F_0 = 100 \) and \( v_0 = 0.02 \).

We use the simulation setting as in Section 4.1. The simulation results are provided in Table 8. As the richer specification in Section 4.1, the results of the SVCJ model also have good finite sample properties. We also note that the 'double-jump' specification includes other widely used option pricing models such as the stochastic volatility model of Heston (1993).

### E.1.2 SVCEJ with variance risk premia

Since the transition equation in the state space representation reflects the dynamics of the latent components, it is, in general, possible to learn the risk premia associated with this latent
process. In this subsection, we provide the Monte Carlo simulation with the variance risk premia (VRP) in the SVCJ model. In particular, we model the VRP \( \pi_v \) as the difference between the mean-reversion parameters under the \( \mathbb{P} \) and \( \mathbb{Q} \) measures, that is, in the state transition equation (E.6) we change the mean-reversion parameter to \( \kappa^\mathbb{P} = \kappa + \pi_v \).

</tbody>
</table>

Table 9 provides the Monte Carlo simulation results for the SVCJ model with VRP. We consider three estimation approaches. First, we fix the VRP parameter to its true value \( \pi_v = 1 \). Second, we assume there is no VRP, although the true model is simulated with non-zero VRP, that is, we fix \( \pi_v = 0 \) in the estimation procedure. Finally, we estimate the VRP along with all model parameters.

As the results suggests, it is hard to identify the VRP in this setting. Potentially, the \( \mathbb{Q} \)-information in the option prices largely dominates the \( \mathbb{P} \)-information making the identification of the VRP hardly possible. A similar issue arises in the term structure literature, where often calibrated bond prices imply unrealistic \( \mathbb{P} \)-dynamics. However, we also notice that in all three estimation settings, the identification of the \( \mathbb{Q} \)-parameters hardly changes. That is, even in the model with VRP fixed to zero, the parameter estimates have good finite-sample properties.
E.1.3 SVCEJ

In the SVCJ model above, the jump sizes are modeled using a Gaussian distribution. Alternatively, we can consider an exponential distribution. Following [Bardgett et al. (2019)], we consider two separate counting processes for negative and positive jumps \( N_t^- \) and \( N_t^+ \), respectively, and modify the SVCJ specification as follows:

\[
\begin{align*}
  d \log F_t &= (-\frac{1}{2} v_t - \mu^- \lambda_t^- - \mu^+ \lambda_t^+) dt + \sqrt{v_t} dW_{1,t} + Z_t^- dN_t^- + Z_t^+ dN_t^+, \\
  dv_t &= \kappa(\bar{v} - v_t) dt + \sigma \sqrt{v_t} dW_{2,t} + Z_t^- dN_t^-,
\end{align*}
\]

(E.7)

(E.8)

where \( \lambda_t^- \) and \( \lambda_t^+ \) are corresponding jump intensities for negative and positive jumps, and \( -Z_t^- \) and \( Z_t^+ \) are exponentially distributed negative and positive jump sizes in log returns with means \( \eta^- \) and \( \eta^+ \), respectively. Note that the negative jump sizes have negative support, that is, \( Z_t^- \) is negative exponential. Given the jump size distributions, the expected relative jump sizes in returns are

\[
\begin{align*}
  \mu^- &= \mathbb{E}[e^{Z^-} - 1] = \frac{1}{1 + \eta^-} - 1 \quad \text{and} \quad \mu^+ = \mathbb{E}[e^{Z^+} - 1] = \frac{1}{1 - \eta^+} - 1.
\end{align*}
\]

We further let the intensities to be affine functions of the stochastic volatility, that is, \( \lambda_t^- = \delta_0^- + \delta_1^- v_t \) and \( \lambda_t^+ = \delta_0^+ + \delta_1^+ v_t \). However, to keep a moderate number of parameters, we set \( \delta_0^- = 0 \) and \( \delta_0^+ = 0 \). This is in agreement with our empirical findings. [Pan (2002)], for instance, also finds the intercept parameter to be close to zero and insignificant. [Andersen et al. (2015)] similarly set these parameters to zero in their model with double-exponential jump sizes. Finally, we allow the volatility to co-jump with negative jumps in returns with exponential jump sizes with mean \( \mu_v \).

This specification is somewhat richer than the SVCDEJ considered in Section 4.1 since the positive jumps are modeled by a separate counting process with its own positive jump intensity \( \lambda_t^+ \). Nevertheless, this specification also belongs to the AJD class and its CCF of the log forward prices has semi-closed form.

The conditional mean and variance of the latent stochastic volatility process are given by

\[
\begin{align*}
  \mathbb{E}[v_{t+1}|\mathcal{F}_t] &= e^{g_1 \Delta t} v_t + \frac{g_0}{g_1} (e^{g_1 \Delta t} - 1), \\
  \text{Var}(v_{t+1}|\mathcal{F}_t) &= -\frac{\sigma^2 + 2\delta^-_1 \mu^- v_t}{2g^2_1} e^{2g_1 \Delta t} v_t - g_0 (1 - e^{2g_1 \Delta t})^2,
\end{align*}
\]

(E.9)

(E.10)

with \( g_0 = \kappa \bar{v} \) and \( g_1 = -\kappa + \delta^-_1 \mu_v \). Equations (E.9) and (E.10) are used to define the state updating equation:

\[
v_{t+1} = c + T v_t + \eta_{t+1}
\]

(E.11)

where \( c = \frac{g_0}{g_1} (e^{g_1 \Delta t} - 1) \), \( T = e^{g_1 \Delta t} \) and \( \text{Var}(\eta_{t+1}|\mathcal{F}_t) = \text{Var}(v_{t+1}|\mathcal{F}_t) \). We also impose the Feller condition \( 2 \kappa \bar{v} > \sigma^2 \) and the covariance stationary condition \( \kappa > \delta^-_1 \mu_v \).

The Monte Carlo simulation results for the SVCEJ model are provided in Table 10. We notice that most of the parameters exhibit good finite sample performance. However, the parameters related to the positive jumps are biased and have large standard deviation.

Note: This table provides Monte Carlo simulation results for the SVCEJ model. We use $T = 500$ time points with $\Delta t = 1/250$. The initial values are set to $F_0 = 100$ and $v_0 = 0.015$. 
E.2 Additional empirical results

Table 11 provides additional empirical results for the same model specification as in Section 4.1. Next to the empirical results with fixed $p^- = 0.7$ in Section 6, we provide the estimates with unrestricted probability of negative jumps and with different fixed values $p^- = 0.65$ and $p^- = 0.75$. Overall, the results indicate similar parameter estimates as in Table 5, suggesting the robustness of our empirical results. We also note larger standard errors of the parameter estimates in the unrestricted model, specifically of the parameter $\delta$ which enters the model as a multiple of $p^-$. This is in line with our simulation results for the unrestricted model (not provided here), which shows the identification limits of the considered unrestricted model. Therefore, in the main empirical results we focus on the restricted model, complementing it with Table 11.

Table 11: SVCDEJ estimates

<table>

</tr>
</tbody>
</table>

Table 12 provides empirical results for the alternative model specification SVCEJ detailed in subsection E.1.3. The SVCEJ specification is richer than the SVCDEJ considered in Section 4.1 since the positive jumps are modeled by a separate counting process with its own positive jump intensity $\lambda^+$. Nevertheless, we can observe a similar magnitude of most of the model parameters, which is reassuring for the robustness of our empirical results.
